SUMMARY

Obstructive sleep apnoea syndrome (OSAS) is a disorder that leads to metabolic abnormalities and increased cardiovascular risk. The aim of this study was to identify early laboratory markers of cardiovascular disease through analysis of oxidative stress in normal subjects and patients with OSAS. A prospective study was designed to compare outcomes of oxidative stress laboratory tests in 20 adult patients with OSAS and a control group of 20 normal subjects. Laboratory techniques for detecting and quantifying free radical damage must be targeted to assess the pro-oxidant component and the antioxidant in order to obtain an overall picture of oxidative balance. No statistical differences in age, sex distribution, or BMI were found between the two groups (p>0.05). There were significant differences in the apnoea/hypopnoea index (AHI) between OSAS patients and the control group (p<0.05). Statistically significant differences in isoprostane, advanced oxidation protein products (AOPP) and non-protein bound iron (NPBI) levels were found between the study and control groups. No significant difference in the levels of thiols biomarkers was found between the two groups. The main finding of the present study was increased production of oxidative stress biomarkers in OSAS patients. The major difference between thiols and other oxidative stress biomarkers is that thiols are antioxidants, while the others are expressions of oxidative damage. The findings of the present study indicate that biomarkers of oxidative stress in OSAS may be used as a marker of upper airway obstructive episodes due to mechanical trauma, as well as a marker of hypoxaemia causing local oropharyngeal inflammation.

KEY WORDS: Obstructive Sleep Apnoea Syndrome • Oxidative damage • Biomarkers of oxidative stress • Polysomnography

INTRODUCTION

Obstructive sleep apnoea syndrome (OSAS) is a disorder that leads to metabolic abnormalities and increased cardiovascular risk. It is characterised by obstruction of the upper airways with repetitive pauses in breathing during sleep and daytime sleepiness, despite efforts made to breathe, and is usually associated with a reduction in blood oxygen saturation. Patients with OSAS are usually unaware of this sleep disruption, but changes in sleep patterns contribute significantly to the prominent symptom of chronic daytime sleepiness typical of these patients.
OSAS has many organic sequelae. Excessive daytime sleepiness impairs quality of life, cognitive performance and social activity. Cardiovascular consequences, such as systemic arterial hypertension, coronary artery disease, heart failure and stroke, are the greatest risks.

The mechanisms hypothesised to explain the association between OSAS and cardiovascular disease are varied and probably interconnected. In fact, repeated episodes of airway occlusion during sleep determine hypoxaemia, hypercapnia and rapid recurrent changes in intrathoracic pressure, triggering a wide variety of autonomic and haemodynamic responses. During episodes of OSAS, intermittent hypoxia determines an increase in oxidative stress that may be involved in the development of cardiovascular disease, vascular injury and endothelial dysfunction. There is much evidence that inflammatory markers, such as oxidative stress, play important roles in atherogenesis and arterial thrombus formation. Patients with OSAS are subject to oxidative stress, due for example to elevated production of reactive oxygen species correlated with high levels of soluble circulating inflammatory factors, such as adhesion molecules. Intermittent apnoea-related hypoxia and post-apnoeic reoxygenation probably contribute to production of reactive oxygen species and inflammatory mediators, triggering upper airway and systemic inflammation. Upper airway inflammation, aggravated by mechanical injury caused by repeated pharyngeal collapse, increases airway obstruction. The systemic inflammatory process also increases release of oxygen-free radicals beyond physiological antioxidant capacity, generating oxidative stress. Various diseases and/or anatomical conditions of the upper airways play a significant role in the ethiopathogenesis of OSAS. The diagnostic technique of Sleep Endoscopy represents the gold standard for the diagnosis of the anatomical sites involved in the pathogenesis of OSAS. The treatment of these particular conditions is uncertain, intermittent apnoea-related hypoxia may be involved, since hypoxia causes sympathetic activation and blood pressure elevations that persists after removal of the hypoxic stimulus. The aim of this study was to identify early laboratory markers of cardiovascular disease through analysis of oxidative stress in subjects without pathological obstruction of the upper airways and patients diagnosed with OSAS.

**Materials and methods**

A prospective study was designed to compare outcomes of oxidative stress laboratory tests in 20 adult patients with OSAS and a control group of 20 normal subjects. The inclusion criteria for the study group were: a) age 18-60 years; b) no previous treatment for OSAS; c) polysomnogram AHI (Apnoea-Hypopnoea Index) > 30. The exclusion criteria were: a) smoking; b) no comorbidities that increase oxidative stress (diabetes, obesity, asthma, nasal polyposis and hypertension). All subjects underwent in the same day: ENT (Ear, Nose and Throat) examination with endoscopy, polysomnography, BMI (Body Mass Index) assessment and evaluation of oxidative stress in plasma sample from fasting venous blood and in urine’s exam. Evaluation of oxidative stress in healthy subjects and patients on pharmacotherapy is indispensable to exclude tissue damage and monitor response to treatment in all conditions involving reactive oxygen species. Laboratory techniques for detecting and quantifying free radical damage must be targeted to assess the pro-oxidant component and the antioxidant in order to obtain an overall picture of oxidative balance. Oxidative stress is now recognised to be involved in the pathogenesis of at least 100 different diseases, including atherosclerosis, emphysema/bronchitis, Parkinson’s disease, muscular dystrophies, preeclampsia, cervical cancer, alcoholic liver damage, diabetes, nephropathy with renal impairment, Down’s syndrome, aging, retinal fibroplasia, cerebrovascular disorders, ischaemia-reperfusion damage and rheumatoid arthritis. Pro-oxidant and antioxidant assays were performed at the Oxidative Stress laboratory of the Neonatal Unit of Siena Hospital.

**NPBI (non-protein bound iron)**

Iron is a versatile and highly reactive element. Having two valencies, iron (II) (ferrous) and iron (III) (ferric), it has access to a wide range of redox potentials spanning the standard redox potential range from +300 to -500 mV. Normally, iron is safely sequestered in transport proteins such as transferrin and lactoferrin and stored in proteins such as ferritin and haemosiderin. As iron ions cannot exist in plasma, the term “free iron” was introduced to indicate a low molecular mass iron form without high-affinity binding to transferrin. A lowering of plasma pH, as occurs during ischaemia (a frequent event in preterm newborns), releases iron, producing free radicals, which release even more iron by mobilising zinc from ferritin. The resulting cascade of iron release and free radical production may cause extensive cell damage.

The method of detection of NPBI in small samples of biological fluids and tissues is based on preferential chelation of NPBI by a large excess of NTA (nitritoltriacetic acid, low affinity ligand). NTA captures all iron bound to low molecular weight proteins and non-specifically bound to serum proteins. It does not remove iron bound to transferrin or ferritin. A two-step filtration procedure was used to separate NPBI: 1) filtration with a 100 kDa MWCO (Molecular Weight Cut-Off) Vecta-Spin Micro-
Whatman ultracentrifuge filter; 2) filtration with a 20 kDa MWCO Vecta Spin Micro-Whatman ultracentrifuge filter at RCF 16.1 and 4°C. The filtrate was injected directly into an isocratic reverse-phase liquid chromatograph after precolumn derivatisation with the high affinity iron ligand 3-hydroxy-1,2-dymethyl-4(1H)pyridone. All glassware and plastic ware was treated to ensure minimum iron contamination.

Protein carbonyls are formed by a variety of oxidative mechanisms and are sensitive indices of oxidative injury. Reactive oxygen species (ROS) cause cell damage, such as oxidation of amino acid residues on proteins to protein carbonyls, leading to alterations in protein structure and amino acid sequence, formation of protein–protein cross-linking and fragmentation of the protein backbone. Carbonyl groups form during normal aging, as well as in neonates receiving oxygen ventilation, and are increased by oxidative stress. Protein carbonyl groups are formed by oxidation of the side chains of lysine, proline, arginine and threonine residues; they are produced as a consequence of oxidative cleavage of the peptide backbone via the amidation pathway or by cleavage associated with oxidation of glutamyl residues. Carbonyl groups can also be formed as a result of secondary reactions of certain amino acid side chains with lipid oxidation products, such as 4-hydroxy-2-nonenal (HNE) or with reducing sugars or their oxidation products.

The quantity of protein carbonyls in a protein sample can be determined by derivatising with dinitrophenylhydrazine (DNPH) and measuring protein-bound DNPH with an anti-DNPH antibody. Protein carbonyl concentrations were determined by enzyme-linked immunosorbent assay (ELISA), by which carbonyls can be quantified with microgram quantities of protein. The assay was set up so that about 1 mg of derivatised protein was applied to each well of the ELISA plate.

Isoprostanes are a series of prostaglandin-like compounds formed by direct ROS attack on arachidonic acid (AA), an unsaturated fatty acid component of cell membranes. Unlike prostaglandins, which are enzymatic products of this fatty acid, isoprostanes are initially formed in situ in cell membranes, from which they are subsequently cleaved by phospholipase. The different pathways for the formation of F2-isoprostanes during oxidation of AA lead to four series of regioisomers (5, 8, 12 and 15 series), which can comprise eight racemic diasteromers. An isoprostaglandin F2α as internal standard. 1 ng of deuterated 15-F2t-IsoP was added to the sample as an internal standard. The sample was then acidified to pH 3 with 1 M HCl and diluted to 3 ml with H2O. The mixture was vortexed and applied to a C18 Sep-Pak column preconditioned with 5 ml methanol and 5 ml water (pH 3). The column was then washed sequentially with 10 ml water (pH 3) and 10 ml heptane. Samples were eluted with 10 ml ethyl acetate/heptane (50:50, v/v). The ethyl acetate/heptane eluate from the C18 Sep-Pak was then dried in a stream of nitrogen and applied to a silica Sep-Pak. The cartridge was washed with 5 ml ethyl acetate and samples were eluted with 5 ml ethyl acetate/methanol (50:50, v/v). The ethyl acetate/methanol eluate was evaporated under a stream of nitrogen. Samples were then converted to pentfluorobenzyl ester with a mixture of 40 μl 10% pentafluorobenzyl bromide in acetonitrile and 20 μl 10% N,N-diisopropylamine in acetonitrile at 37°C for 30 min. The reagents were dried under nitrogen and the residue eluted on TLC with 50 μl methanol. Compounds migrating in the region of the methyl ester of PGF2α (Rf 0.22) and the adjacent area 1.1 cm above were scraped and extracted from the silica gel with ethyl acetate. The ethyl acetate was dried under nitrogen and the isoprostanes redissolved in 20 μl undecane for analysis by GC/MS (Gas chromatography–mass spectrometry). For quantification purposes, we compared the height of the peak containing the derivatised 15-F2t-IsoP (m/z 569) with the height of the deuterated internal standard peak.

Thiol production was measured with the -SHp test (Diacron International, Italy) 28 29. Thiols are a qualitatively significant component of the antioxidant plasma barrier. Indeed, thiol groups (-SH) of plasma compounds (e.g. proteins, P-SH) oppose the propagation step of radical chain reactions by inactivating alkoxyl radicals (RO*), according to the reaction:

2 P-SH + 2 RO* → 2 PS* + 2 ROH → P-S-S-P + 2 ROH

They also neutralise the tissue-damaging action of hydroxyl radicals (HO*), according to the reaction:

2 P-SH + 2 HO* → 2 PS* + 2 H2O → P-S-S-P + 2 H2O

From a merely stoichiometric point of view, a pair of thiols reduces a pair of alkoxyl (RO*) or hydroxyl (*OH) radicals by exchanging two electrons (as hydrogen atoms), inactivating the radicals. Indeed, alkoxyl and hydroxyl radicals are transformed to alcohol and water, respectively, while the thiol groups, now oxidised, react among themselves, forming disulphide bonds. The -SHp test is based on the ability of thiol groups in a biological sample to develop a photometrically-detectable coloured...
complex (maximum peak of absorbance, 405 nm) in an adequately buffered solution (R₁ reagent of the kit) by reacting with 5,5-dithiobis-2-nitrobenzoic acid (DTNB), which is dissolved as a chromogenic mixture (R₂ reagent of the kit). The intensity of photometrically-detected colour is directly proportional to the concentration (or title) of thiols, according to the Lambert-Beer law. Continuous variables were analysed using a Student’s t test. All tests were two-tailed, and p values of <0.05 were taken as statistically significant. Data is presented as mean ± standard deviation or as mean/median with range, as appropriate.

Ethical standards
The present study was approved by the Ethics Committee of the University of Siena and were performed in accordance with the ethical standards laid down in the 1964 Declaration of Helsinki and later amendments. All persons gave their informed consent prior to inclusion in the study.

Results
Demographic and clinical data of the study population and control group are shown in Table I. No statistical differences in age, sex distribution, or BMI were found between the two groups (p > 0.05). There were significant differences in AHI between OSAS patients and the control group (p < 0.05). Statistically significant differences in isoprostane levels were found between the study and control groups (67.35±40.02 vs 21.19±14.71, p < 0.0001; Fig. 1). AOPP (Advanced Oxidation Protein Products) levels were significantly higher in the OSAS group (111.97±24.44 vs 19.53 ±6.85, p < 0.0001; Fig. 2). Statistical differences in NPBI were found between the two groups of patients (3.01±2.21 vs 0.69±0.83, p = 0.0014; Fig. 3). No significant difference in the levels of thiol biomarkers was found between the two groups (488.80 ±65.27 vs 489.1±58.15, p = 0.6733; Fig. 4). Significantly higher urine isoprostane levels were found in OSAS group (216.78±244.22 vs 1.13±0.12, p < 0.0001; Fig. 5).

Discussion
OSAS is a major risk factor for cardiovascular and cerebrovascular disease. The mechanisms involved in the pathogenesis of OSAS include oxidative stress, systemic inflammation and endothelial dysfunction. The main finding of

the present study was increased production of oxidative stress biomarkers in OSAS patients. Since biomarkers are inflammatory markers, this finding is in line with previous studies showing inflammation of the pharynx, uvula, soft palate and oral cavity of OSAS patients. Various studies have outlined the role of inflammation markers as indirect markers of upper airway obstructive episodes. A correlation has been demonstrated between oral nitric oxide and OSAS severity due to local oropharyngeal inflammation caused by mechanical trauma and hypoxaemia. Oral inflammation in OSAS is thought to originate in the upper airways, where repetitive closing and opening during apnoeic episodes leads to increased production of inflammatory cytokines. Oral inflammation in OSAS may also be a consequence of intermittent hypoxia and reperfusion. The increased levels of oxidative stress biomarkers may arise from the recurrent episodes of hypoxia, while subsequent inflammatory status and reperfusion damage are cofactors that may lead to a further increase in these biomarkers.

Our results showed significant differences in the levels of the biomarkers studied in the two groups of patients, apart from thiols, which did not show any difference between patients and controls. The main difference between thiols and the other oxidative stress biomarkers is that thiols are antioxidants, while the others are expressions of oxidative damage. Thiols are a qualitatively significant component of the antioxidant plasma barrier. Indeed, thiol groups of plasma compounds (e.g., proteins, P-SH) oppose the propagation of radical chain reactions by inactivating alkoxyl radicals. The similar levels of thiols found in the two groups confirm the homogeneity of the two study populations, since no patient was taking antioxidant drugs or had manifest cardiovascular disease that may have led to reduced expression of antioxidants. Furthermore, thiol levels may be a late rather than an early marker of oxidative stress.

The results showed 100% specificity for all biomarkers analysed, and 100% and 95% sensitivity for protein carbonyl and urine isoprostanes, respectively (Tab. II). Plasma isoprostanes and NPBI showed 60-70% sensitivity. In conclusion, the findings of the present study indicate that biomarkers of oxidative stress in OSAS may be used as a precursor marker of upper airway obstructive episodes due to mechanical trauma, as well as a marker of hypoxaemia causing local oropharyngeal inflammation. Increased oxidative stress may have important clinical implications in OSAS patients in terms of diagnostic, therapeutic and prognostic aspects. The aim of the present study was to evaluate the levels of oxidative stress indicators in OSAS patients and a control group. It will be important investigate whether the levels and activities of these markers are correlated with demographic, biochemical, metabolic and polysomnographic parameters. By amplifying oxidative and nitrosative stress, oxidative biomarkers may have a pathogenic role in OSAS.

**Conclusions**

The findings of the present study indicate that biomark-
Oxidative stress in patients with obstructive sleep apnoea syndrome

Oxidative stress in patients with obstructive sleep apnoea syndrome may be used as a marker of upper airway obstructive episodes due to mechanical trauma, as well as a marker of hypoxemia causing local oropharyngeal inflammation.
