SUMMARY

In the last 20 years, neonatal survival has progressively increased due to the constant amelioration of neonatal medical treatment and surgical techniques. Thus, the number of children with congenital malformations and severe chronic pathologies who need rehabilitative care has progressively increased. Rehabilitation programs for paediatric patients with disorders of voice, speech and language, communication and hearing, deglutition and breathing are not widely available in hospital settings or in long-term care facilities. In most countries, the number of physicians and technicians is still inadequate; moreover, multidisciplinary teams dedicated to paediatric patients are quite rare. The aim of the present study is to present some new trends in ENT paediatric rehabilitation.

KEY WORDS: Children • Rehabilitation • Sinusitis • Laryngeal paralysis • Choanal atresia • Aural atresia • Music • Voice • Cochlear implant

Introduction

In the last 20 years, neonatal survival has progressively increased due to the constant amelioration of neonatal medical treatment and surgical techniques. These aspects have produced an increased incidence of children with congenital malformations and severe chronic pathologies. Moreover, the immigration of children from underdeveloped countries, where perinatal infections or other risk factors are still high, have further increased the number of paediatric patients who need rehabilitative care. It is worth noting that among over 50,000 scientific papers in the literature regarding paediatric rehabilitation, only about 1000 are related to ENT arguments. Thus, rehabilitation of paediatric patients with disorders of voice, speech and language, communication and hearing, deglutition and breathing is generally still inadequate to the real needs and rarely is well organised with multidisciplinary teams, working both in the hospital setting and in long-term care facilities. The aim of the present study is to present some new trends in ENT paediatric rehabilitation.

Chronic rhinosinusitis

Rhinosinusitis is a very common condition and its prevalence has increased in recent years in both children and the adult population. By definition in chronic rhinosinusitis (CRS), symptoms last more than 12 weeks. Antibiotics are the most frequently used therapeutic agents in acute rhinosinusitis (ARS). Uncomplicated ARS, if no allergies exist, can be treated with amoxicillin (40 mg/ kg/day or 80 mg/kg/day). Other reasonable choices are amoxicillin/clavulanate and cephalosporins. If hypersensitivity to any of the above antimicrobials is suspected, alternative choices include trimethoprim/sulfamethoxasole, azithromycin, or clarithromycin. Surgical intervention in the treatment of nasal polyps is considered in patients who fail to improve after a trial of maximal medical treatment or in patients presented at diagnosis with antrochoanal polyp, cystic fibrosis (CF), Kartagener and Churg-Strauss syndromes. Functional endoscopic sinus surgery (FESS) involves the clearance of polyps and polypoid mucosa and opening of the sinuses ostia. If maximum medical therapy is unsuccessful in a
child with chronic or recurrent sinusitis, evaluation for underlying medical disorders (e.g. immunodeficiency, allergic rhinitis, CF and immotile cilia syndrome) is warranted. Surgery consisted of adenoectomy with or without antral irrigation and balloon sinus dilation, and FESS 3. Follow-up begins after surgery and can last for years; it is performed with nasal endoscopy and inspection of breathing spaces, eventual nasal secretions, healing of nasal mucosa, natural ostium and sinusotomy patency. In the first visit after FESS, there is removal of nasal packing; it is normally performed one or two days after surgery. Further visits are made at 15 days and one month after surgery: the goal is inspection of nasal cavities and removal of nasal crusting and fibrinous exudate to prevent nasal adhesions. If no complications exist, clinical follow-up visits are scheduled 3-6 and 12 months after surgery and are made to prevent late complications and relapse. Recurrence rates are higher in nasal polyposis stage IV and V (association with CF, Kartagener and Churg-Strauss syndrome). In these cases, there is no definitive treatment for nasal polyposis and long follow-up is necessary. In the youngest patients, endoscopic medications must be scheduled in sedation or under general anaesthesia: parents should be previously informed about this requirement and the fact that these are not new surgical interventions, but are necessary to improve the first result. All children with CRS should be submitted to allergy tests. Tests for immunodeficiency should be done in children with chronic recurrent disease, poor response to medical interventions, but are necessary to improve the first result. All children with CRS should be submitted to allergy tests. Tests for immunodeficiency should be done in children with chronic recurrent disease, poor response to medical interventions, but are necessary to improve the first result.

Choanal atresia rehabilitation in paediatric patients

Choanal atresia is defined as a congenital obstruction of the posterior nasal choanae. It represents one of the most frequently observed congenital nasal defects, with a prevalence of 1:5,000-8,000 live births 5. In about 50% of cases it occurs bilaterally, thus constituting the main indication for sinonasal surgery in the newborn 6. The association of choanal atresia with craniofacial and genetic syndromes is well known. In particular, between 7% and 29% of patients with choanal atresia are affected by CHARGE syndrome. In these conditions, the atresia presents often bilaterally (Fig. 1) 5. Bilateral choanal atresia presents with respiratory distress in the immediate neonatal period. The crises are typically alleviated when the child begins to cry. Surgical intervention is considered the main therapeutic option. Over the decades, various surgical techniques have been described 7-9. An “ideal” surgical technique should ensure adequate choanal patency and low restenosis rates, should spare the surrounding anatomical structures and provide low rates of morbidity and mortality. It should also ensure the shortest time hospitalisation 8.

Nowadays there is still a lack of randomised controlled studies comparing the efficacy of the different surgical approaches, but it is common expert opinion to consider an endonasal endoscopic approach to be the least invasive and probably the safest in terms of compliance 9. However, restenosis remains the most frequent complication in choanal atresia surgery, with a prevalence between 9% and 36%. Adjuvant measures have been introduced to reduce the restenosis rate: nasal stenting, mitomycin C and balloon dilatation. The use of nasal stenting is still debated 10.

A stent is generally applied to stabilise postoperative outcomes, but this procedure entails some worrisome complications. Nasal and nasopharyngeal infections, mucosal ulcerations, tissue ischaemia and necrosis and formation of granulation tissue are only some of the possible consequences of long-term use of a nasal stent 10,11. Recently, some authors performed stentless choanal endoscopic surgery repair. To date, a total of 42 procedures have been carried out, with a restenosis rate of only 38% 11-13. Nasal irrigation in the postoperative period is crucial for maintaining neo-choanal patency, in association to endoscopic medications according to a precise follow-up schema. In our centre, nasal packing is removed 24 hours after the surgical procedure, the first postopera-
Obstructive sleep apnoea

Sleep disorders include different conditions ranging from primary snoring to obstructive sleep apnoea (OSA). OSA is characterised by both partial and complete airway obstruction, which induce hypoxaemia with a relevant decrease in quality of the sleep and day life. OSA in children has a prevalence between 1.1% and 2.9% 15. The diagnostic gold standard in OSA syndrome is overnight polysomnography, but home pulse oximetry has also been proposed as a screening test 16. Adenotonsillar hypertrophy is the most important aetiologic factor for OSA in paediatric patients: nearly 45% of OSA children are affected by lymphatic Waldenström’s ring hypertrophy 17. Adeno-tonsillectomy is therefore indicated as a first therapeutic option in OSA children without other important comorbidities and has shown good efficacy in improving the patients’ quality of life 18. However, the degree of adenotonsillar hypertrophy is not strictly related to the severity of respiratory sleep disorder. Predictors for a persistent elevated postoperative apnoea-hypopnoea index (AHI) are: age > 7 years, BMI increase, preoperative AHI > 20 and asthma. As reported by Albera et al. in a large cohort of paediatric patients, more OSA children presented with impaired swallowing function and impaired speech articulation in comparison to non-OSA patients. Interestingly, adeno-tonsillectomy improved obstructive respiratory function in the first group of patients, but did not modify secondary dysfunctions such as atypical swallowing, oral breathing, or dyslalia 19.

A rehabilitative programme is necessary in addition to surgical or medical therapy for OSA. No standardised protocols are reported to date 20. The speech therapy centre in Rome has proposed a valid rehabilitation scheme, which consists of neuromuscular and myofunctional therapy for oro-facial musculature 21.

Laryngeal paralysis

Laryngeal paralysis (LP) is the second most common laryngeal congenital malformation after laryngomalacia. Of all laryngeal malformations, its prevalence is about 15-20%. Unilateral LP (48%) may cause swallowing impairments and chronic food inhalation; depending on the position of fixation of the vocal cords, bilateral LP (52%) may present with respiratory symptoms varying from inspiratory stridor to acute respiratory distress with cyanosis. The latter condition requires emergent tracheal intubation 22.

A flexible fibrescope is routinely used in the diagnostic workup of LP. It is performed without anaesthesia, thus allowing direct visualisation of laryngeal motility. Possible underlying associated malformation, which is present in about 45% of LP cases, is investigated with a rigid laryngo-tracheo-bronchoscope under general anaesthesia. Only after both central and peripheral causes of vocal fold paralysis have been excluded, the condition can be defined as idiopathic. In severe cases of LP, when the risk of liquid inhalation occurs, it is necessary to place a nasal-feeding tube. In addition, tracheostomy is required in 8% and 53% of cases of unilateral and bilateral LP, respectively 22.

Above all, idiopathic LP may partially spontaneously resolve within the 6th-12th month of life. When there is no evidence of improvement in laryngeal motility after the age of 2 years, the lesion could be defined persistent. At this point, surgical intervention is required to create adequate respiratory space. A posterior cordectomy is generally performed 23. Logopaedic rehabilitation (LR) is indicated in unilateral LP with the aim of inducing a spontaneous compensation of vocal fold motility. The earlier LR is begun, the better the functional results that might be obtained. Moreover, LR finds application in children who underwent tracheal tube or nasal-feeding tube placement. Long lasting tracheal intubation (> 48 h), as well as nasal-feeding tube application, can provoke vocal and swallowing dysfunctions when removed. Tracheostomy, moreover, affects laryngeal motility in indirect ways, determining deafferentation of the proprioceptive innervation in the transglostical area and progressive muscular atrophy 24. A LR programme is defined on the basis of symptoms. Plurisensorial stimulation touches all the structures involved in respiratory, vocal and deglutition functions.

Juvenile laryngeal papillomatosis

Juvenile laryngeal recurrent papillomatosis (JRRP) is a rare viral disease caused by HPV-6 and HPV-11 infection. Both single and multiple lesions of JRRP affect especially the glottic region but, in 5-28% of cases, may also extend caudally into the tracheobronchial three and lungs 25. The papillomatosis glottic involvement entails important functional and vocal consequences, with significant impact on the emotional and behavioural sphere of children, and consequently their quality of life.

Although in JRRP the goal of treatment is obtaining adequate respiratory airway patency to avoid tracheostomy, it is also of utmost importance to define suitable surgical treatment protocols to reduce the incidence of iatrogenic vocal damage. The intensity of voice function alteration correlates with the number of surgical procedures per person, and not with age at diagnosis 26. Consequently, voice function preservation surgery should preserve as much healthy l-
ryngal mucosal tissue as possible, without reaching radical excision. The gold standard treatment is a mini-invasive approach with CO₂ laser or microdebrider surgical excision of lesions, associated or not to adjuvant virostatics 27. Only one prospective cohort study in 11 patients compared vocal function outcomes of the two surgical techniques. Main vocal outcomes included overall severity rating, jitter, shimmer and noise-to-harmonic ratio. “Cold” dissection with a microdebrider resulted in better immediate and early postoperative voice outcomes in children. Additionally, increased exposure to CO₂ laser correlated with worsening voice quality. This can be explained by the potential thermal injuries of the surrounding and deeper tissues induced by the laser 28.

Long-term soft tissue complications including scarring, stenosis and web formation can also lead to voice disorders. The total number of repeated microsurgical interventions performed per patient and the lesion site influences the rate of these complications. The most frequent laser-induced soft tissue complication is anterior glottic web 29. The rate of soft tissue complications is influenced not only by the total number of repeated surgical interventions per patient, lesion site, surgical technique, age at diagnosis and advanced stage of disease, but it also correlates with the presence of gastro-oesophageal reflux 29.

The main functional aim in JRRP surgery is therefore avoiding soft tissue deep laryngeal damage in order to prevent voice function injuries in children. A “cold” dissection of the glottic lesions sparing the lamina propria, healthy surrounding tissue and glottal deeper laryngeal structures seems to be the right direction. The use of a microdebrider is reaching increasing consent in this field. However, in literature there are no prospective randomised studies to support the superiority of the microdebrider surgical technique. In the future, the use of tetravalent HPV vaccine might represent a promising option.

Breathing rehabilitation in patients with laryngo-tracheal axis stenosis

The most frequent diseases causing laryngo-tracheal stenosis in the paediatric population and requiring breathing rehabilitation are: laryngomalacia, vocal cord paralysis (monolateral or bilateral), hypoglottic stenosis, tracheal stenosis and tracheomalacia.

Laryngomalacia is a congenital abnormality of the laryngeal cartilage. It is a dynamic lesion resulting in collapse of the supraglottic structures during inspiration, leading to airway obstruction. It is thought to represent a delay of maturation of the supporting structures of the larynx 30. If present, reflux can worsen breath symptoms 31. Laryngomalacia is the most common cause of congenital stridor and is the most common congenital lesion of the larynx. Diagnosis is made by flexible naso-pharyngo-laryngoscopy under topical or no anaesthesia, followed by direct laryngoscopy under general anaesthesia (without muscle relaxant). In order to complete the staging, pulmonary function tests (PFTs) and polysomnography (PSG) are mandatory 31. Spontaneous resolution of symptoms is the rule; it usually occurs by the age of 2-5 years, so the main treatment consists in antireflux drugs and follow-up. Surgical intervention is indicated only in severe cases (10-12% of all cases) of laryngomalacia and consists in endoscopic approaches, namely supraglottoplasty. The aim of surgery is to correct the anatomical cause with minimal tissue damage. A cold steel technique is recommended. Other instruments have been used including laser and microdebriders.

In recent years, paediatric breathing physiotherapy uses various techniques to help removal of mucus from the airways and improvement of pulmonary function. These are: cough, compressions/vibrations, forced expiratory technique (FET), autogenic drainage (AD), prolonged slow expiration (PSE), positive expiratory pressure (PEP), positive continuous periodic pressure (PCPAP), continuous positive airway pressure (CPAP), physical exercise, aerosol and nasal unblocking. Evaluation of patient posture is another important issue: chest conformation, postural alignment (chin, shoulder, thorax position) and spine alignment on frontal and sagittal plane. The main goal of breathing treatment is removal of airway secretions, where physiological clearance mechanisms (cough, cilia, ventilation) are ineffective.

Paediatric tracheostomy: a changing trend

In the last 30 years, the role and the indications for tracheostomy have remarkably changed. The most common indications for paediatric tracheostomy have passed from infective causes (epiglottitis, croup, diphtheria) to airway obstruction and anomalies 32, long-term ventilation requirement and underlying neuromuscular or respiratory problems 33. Long-term intubation is now the first indication for tracheostomy; in the absence of guidelines, the majority of authors agree to perform a tracheostomy after 2-3 weeks of intubation to avoid hypoglottic or tracheal stenosis 34. A literature review shows that 50% of patients with tracheostomy is less than one year old. This is related to the improvement of the Paediatric Intensive Care Unit (PICU) that allows more premature babies survive, but at the same time it entails greater risk of complications for the smaller diameter and the lower stiffness of the trachea. More generally, there has been in recent years an increase of late complications of tracheostomy, related to the prolonged presence of the tracheostomy tube. These late complications are peristomal granulomas, tracheal stenosis, trachea-innominate fistula, tracheo-oesophageal fistula and trachea-cutaneous fistula.

The surgical procedure is more complicated in the paediatric population. Open surgical tracheostomy and percutaneous dilatational tracheostomy, described by Ciaglia in 1985 35, are two possible approaches in the adult population.
There are different types of tracheostomy tubes that vary in certain features for different purposes; they can be made in plastic, silicon, PVC and metal. For the first application, it is generally suggested to use a plastic tube. The length and angle of the tube should be such as to maintain its end portion in axis with the trachea. The American Thoracic Society suggests selecting a tube of such a length as to extend to 2 cm below the stoma and at least 1-2 cm from the carina 36. The National Guideline Clearinghouse (NGC) 37 recommend that skin care of the stoma and under the tracheostomy ties be provided at least daily, and more often if indicated, to prevent pressure necrosis and to maintain intact, clean and dry skin. Tracheostomy tube suctioning should be performed at least twice daily and as needed, based on clinical assessment to assure tracheostomy tube patency (ATS). It is recommended that tracheostomy tube changes are performed routinely by institutional standards to maintain airway patency; the first change is made within 5-7 days for surgical tracheostomy and within 10-14 days for percutaneous tracheostomy. The further changes are routinely made every 2-4 weeks according to the Cincinnati Children’s Hospital Center (CCHMC) guidelines 38. There is insufficient evidence and a lack of consensus to make a recommendation on the use of heated versus cool humidification in prevention of mucous plugging (ATS). According to AAO-HNSF decannulation can be made if clinically there is resolution of the primary disease, no active infection, tolerance of the speaking valve, endoscopically there is a clear tracheobronchial tree without suprastomal granuloma and functionally if there is an adequate cough reflex. The process of decannulation needs observation for 24-48 in a monitored setting 36. Every child with tracheostomy should be referred to a phoniatric clinic for evaluation of the phonation and deglutition. Rehabilitation of speech relies on phonatory valves, signs language, laryngophone and fenestrated tracheotomy tubes. Evaluation of the deglutition to rehabilitate the patient for feeding is made with administration of methylene blue solution under videolaryngoscopy and with scintigraphic study of deglutition.

Dysphagia following laryngo-tracheal reconstruction

The laryngeal anatomical structures involved in swallowing are epiglottis, laryngeal vestibule and vocal folds 39-40. Anatomical alterations of upper airways causing stenosis may prevent coordinated process of swallowing, affecting its efficiency and safety 41. Surgery designed to restore the airway in laryngo-tracheal anomalies can cause or exacerbate the alterations of swallowing mechanisms and interfere transiently or permanently on airway protection mechanisms causing dysphagia. Surgery of the airway include both endoscopic (epiglottoplasty, dilatations and balloon surgery, vocal fold lateralisation, partial arytenoidectomy, closure of laryngo-tracheo-esophageal cleft, posterior cordotomy) and open surgery (laryngotracheoplasty for airway dilatation, laryngotracheal reconstructions, cricotracheal resection with removal of stenotic tract and termino-terminal anastomosis).

The difficulties in feeding and swallowing after laryngo-tracheal reconstruction are multifactorial and to be able to make a rehabilitative project is mandatory understand the reason of these difficulties. There are specific and non-specific factors that contribute to the disease. Non-specific factors are basic diagnosis, health status of the baby and type of surgery which has undergone. Specific factors can be further divided in immediate and delayed. The immediate factors are anatomical structure transformation, altered protection of airway and presence or absence of the tracheostomal tube. The delayed factors are development of sensory skills, acceptance of feeding aids, acceptance of food more consistent, development of oral motor skills like chewing, adjusting meal times and appropriate eating behaviour.

Considering the importance of swallowing and breathing for general health and in the quality of life of the child, it is very important to manage these diseases with a multidisciplinary approach involving surgical, medical and rehabilitative features 42.

In the literature, there are many studies that stress the importance of evaluating feeding and swallowing skills of the child before and after surgery; this is done to better understand the functional ability of the child and understand if the swallowing problems are related to the basic diagnosis or a consequence of the surgery on anatomical structures 43-45. The evaluation protocol includes the presence of alternative nutrition; evaluation of the different mechanisms of sensory and motor parts of deglutition; assessment of the management of oral secretions; the evaluation of the mechanisms of sucking/chewing and swallowing; breathing during the meal; and the amount of food administered. If swallowing function will be evaluated with instrumental tests, the child may undergo a video-fluoroscopic swallowing exam.

The goal of preoperative evaluation is to understand the anatomical and physiological factors that determine any difficulty feeding in order to react appropriately and quickly in the postoperative period. After intervention, assessment will be carried out to evaluate the results and make a rehabilitation plan with the objective of recovering the best features. The rehabilitation project must be customised and targeted, and should not only take into account swallowing function, but also respiratory function, and must include weaning from tracheal cannula if de-cannulation is possible, or use of speech valve.

Voice rehabilitation in children: two different possible protocols

The Voice Craft method (Estill Voice Training) was established in 1988 by American singing voice specialist Jo Estill and is characterised by a series of vocal manoeuvres to develop specific control over individual muscle
groups within the vocal mechanism. Training comprises 13 vocal exercises or compulsory figures. Each ‘figure’ establishes control over a specific structure of the vocal mechanism, in isolation, by moving the structure through a number of positions. The most important compulsory figure is probably the false vocal folds control, which identifies three possible positions of the false vocal folds: constricted, mid and retracted. Moreover, Estill Voice Training incorporates six ‘voice qualities’ as mechanisms for demonstration of voice production control. The six voice qualities are speech, sob, twang, opera, belting and falsetto. A protocol of 12 training sessions for the voice rehabilitation in children has been described by Fussi and Turlà. In the first session, children and parents cooperate in collecting clinical history and receiving together initial and simple counseling about vocal hygiene and possible consequences of voice disorders. Children receive a diary to note correct or un-correct vocal use during the day every evening. During the second session, several relaxing and stretching exercises are carried out. Perceptive training (starting from the intensity parameter) is taught during the third session, using specific games and exercises. The fourth and fifth sessions are dedicated to correct breathing and pneumo-phonico-coordination. These aspects are generally boring to children and need to be taught through different games (soap balls, wind imitation, etc.). The sixth session is dedicated to control of the correct acquisition of breathing and to further auditory perception training on intensity and pitch. In the seventh session exercises of articulation and exercises to experiment and perceive vocal tract resonance are proposed. Several nasalisation and chewing movements are explained. During the eighth session, children are invited to sing a simple tune using different modalities of voice productions, correct breathing and coordination, hyperarticulation etc. The basic vocal qualities described in the Estill method are explained in the ninth lesson: speech, sob, belting and twang. During the 10th and 11th lessons, children must produce the different voice qualities by imitating several cartoon characters. Finally, during the last session participants are involved in dramatising a simple story by using different voice qualities and productions, depending on the specific context of the story. Post-treatment evaluation generally demonstrates that children have acquired better consciousness of their voice instrument, use different voice modalities depending on the specific situation, significantly reduce vocal abuse and enjoy in playing with their voice.

The aim of the “Proprioceptive-Elastic Voice Rehabilitation Program” (PROEL) (Fig. 2) is to achieve a relaxation of muscle stiffness and to obtain elasticity through facilitating postures, unstable balance, and body movement. The method of work is “experimental”: a hoarse patient compares his/her voice before and after exercise, and thus makes an “impression” on the brain that allows them to internalise a “phonatory pattern” correctly. Perception training is thus fundamental even in the PROEL method: children should become conscious of their voice qualities, of the mechanisms of voice production, how to use the voice in the different daily situations and how to avoid voice fatigue. Rehabilitative training should be considered completed when the child has perfectly consolidated the correct use of voice in relation to total body, is able to recognise the possible risk factors for his/her voice and is able to self-correct voice misuse or abuse without an external guide. The PROEL method has been modified by De Maio et al. for optimal use in paediatric dysphonic patients. Ludic activities, on several occasions chosen by the young participants themselves, have demonstrated to be useful in improving voice production and enjoyable by the children.

A new instrument for the evaluation of the benefits obtained with different treatments for the voice disorders in children is the Children Voice Handicap Index 10 questionnaire (CVHI-10). This questionnaire is easily administered, highly reproducible, with good clinical validity and responsiveness to treatment.

Aural atresia rehabilitation

Patients with bilateral atresia should have either a softband BAH (Bone Anchored Hearing Implant) or a conventional headband bone conduction hearing aid in early life to provide adequate stimulation for development of the central nervous system. When the child grows older, percutaneous BAH becomes an option, usually by 5 years old. The surgical technique has been recently simplified with the linear incision (Fig. 3), instead of the skin flap technique. Canalplasty is a choice for selected candidates after the age of 8. The anatomy of the temporal bone is a major confounding factor in the approach of hearing rehabilitation. Patients with good middle ear anatomy (Jahrsdoerfer score 7 or above) may be suitable for canal reconstructions, although this kind of surgery is less frequently carried out than in the past. In most studies comparing BAH and patients with EAC recon-
struction, BAHI has generally resulted in significant hearing gain vs. reconstruction. The mean postoperative speech reception threshold is 25-35 dB HL, which is the range of mild hearing loss and around 30% of patients still need a conventional hearing aid to assist with hearing after surgery. In addition, otologists are often frustrated with the relatively common occurrence of restenosis and recurrent infections of the canal (Fig. 4). The reported rate of restenosis ranges from 5 to 29% and around 26% of the population requires re-operation. Serious complications may also occur during this surgery, such as worsening of hearing loss and facial nerve palsy in 1% of cases, as up to 30% of this group of patients have an anomaly in the course of their facial nerve.

Vibrant sound bridge (VSB), on the other hand, is implanted inside one middle ear, which provides unilateral stimulation to the inner ear system. This unilateral direct inner ear stimulation completely removes the possibility of signal confusion. VSB is a middle ear implant consisting of two parts, the external audio processor (EAP) and the implantable vibrating ossicular prosthesis (VORP). The EAP picks up sound signals, amplifies them and transmits them to the VORP. The floating mass transducer (FMT), in the distal part of the VORP, vibrates the attached middle ear structure through a single point of attachment and thereby stimulates the cochlea.

In aural atresia patients, the FMT can either be attached to the stapes, if it is functioning, or to the round window, in which case the procedure is known as round window vibroplasty. During VSB implantation, the usually malformed middle ear cleft has to be entered to insert the FMT. It carries a risk of injury to facial nerves and the inner ear, while no such complications occur in BAHI.

Bonebridge (BB) was initially designed for patients over 18 years old because a certain thickness of the cortical bone is required. Despite some reports of successfully implanted paediatric patients, this procedure requires a great deal of caution.

For those with unilateral disease, time is allowed for a thorough discussion and consideration of treatment options. In fact, it has been well established that patients with unilateral hearing loss may have difficulties in communication and at least 25% of the patients’ parents and teachers report behavioural problems and academic performance issues. There is still controversy about how much we should do for patients with unilateral congenital aural atresia. Restoring binaural hearing can avoid the development of an ear dominance syndrome and numerous studies have shown that it brings more benefits than harm, including better hearing in noise, improved distance hearing and elimination of head-shadowing. However, to avoid a dominant syndrome, binaural hearing should be promptly restored, most probably in the first years of life. As every patient’s needs and expectations vary, detailed discussion should take place to achieve the best solution for each individual case.

In some patients who need repeated magnetic resonance imaging (MRI), for example in patients with neurological diseases, the method of hearing rehabilitation has to be carefully considered. This is because MRI is generally not recommended for patients with implantable hearing aids, like VSB. BB can tolerate MRI scanning up to 1.5 tesla and BAHI up to 3 Tesla. These implants also produce artifacts in images of the brain. BAHI is the least disturbing due to its small implant size.

In summary, most patients with aural atresia benefit from hearing rehabilitation. The choices are conventional headband bone conduction hearing aid, softband BAHI, canalplasty, percutaneous BAHI, VSB and BB. Each option has its strengths and weaknesses. Early identification and referral for further management are key to obtain a successful long-term outcome.
Cochlear implant

Cochlear implant in children is a safe procedure with a low risk of complications as largely reported in recent literature. Immediate and late complications are not significantly different when surgery is carried out before one year of age, with respect to 12-18 months (P = 1). Moreover, anaesthesiological complications are rare, probably ranging from 0 to 1.5 %, even in syndromic patients. Early implantation is believed to enable the maximal development of communication skills, social exchange and cognitive abilities. The lower age limit of implantation is therefore not related to surgical or anaesthesiological considerations, but to the consideration that very early audiological diagnosis is not always reliable, even when established at tertiary centres, and not all children identified as suffering from sensorineural hearing loss (SNHL) will have permanently impaired threshold levels. The absence of any electrophysiological or behavioural reaction to sound does not always reflect SNHL. Bovo et al. have recently described a case series of 23 newborns with a diagnosis of severe-to-profound hearing loss at three months, who significantly improved even reaching a normal auditory threshold during the first year of life. All the full term neonates showed a significant improvement in their initial threshold within 6 months of age. On the other hand, in most of the premature newborns the initial signs of threshold amelioration occurred beyond 70 weeks of gestational age, and even beyond 85 weeks in one case. The authors assumed that when severe-to-profound SNHL is confirmed and persistent after appropriate follow-up tests for 6-8 months, cochlear implantation can be carried out with no risk of diagnostic error in term-born infants. On the contrary, follow-up for severely pre-term babies should last up until no less than 80 weeks of gestational age. The lower limit of age must not be respected in all cases of post-meningitic deafness or in other causes of cochlear fibrosis and calcification.

Music rehabilitation in children with hearing aid and cochlear implant

According to Ford, “the capacity to perceive and assimilate music resides in the brain, and although hearing loss may impose certain limitations upon the extent to which musical potential is realised, it does not negate the presence of innate musicality”. Furthermore, Darrow stated that “for the deaf or hard of hearing children, music can be in some ways more aurally accessible than speech”. There is today a general agreement that these children can enjoy and participate in music activities and can increase their aesthetic sensitivity. Nevertheless, it is to be considered that among the three cardinal elements of music, i.e. rhythm, melody and timbre, in most hearing aided or implanted deaf children only rhythm perception is reported to be similar to that of listeners with normal hearing. In fact, even with technically sophisticated multiple-channel sound processors, recognition of melodies is poor, with performance at little better than chance levels for many implant users. This can also be observed when the tunes are familiar and are played as a sequence of isolated notes without accompaniment or harmony. Thus, discrimination of music interval, tone sequences with ascending or descending notes, or simple melodic structures are greatly deteriorated abilities in profound deaf children. On the other hand, one should consider that often the concepts of high and low are difficult even for hearing students who confuse the term with loud and soft. Nevertheless, the ability to differentiate between notes is necessary to study and learn melodies. Perception of timbre, which is usually evaluated by experimental procedures that require subjects to identify musical instrument sounds, is also generally unsatisfactory. Only the discrimination of the different groups of musical instruments is generally possible (i.e. string-, wood-, brass-, percussion-instruments), while recognising a single instrument among its group is very difficult. Despite all these limitations, Hash stated, “Considering an ‘average’ profound hearing loss, the motivated student is capable of learning to play an instrument to at least an intermediate level”. Some instruments will be easier for the student who is deaf or hard of hearing to learn, but under the right conditions nearly all are audible over most of their ranges. Generally, instruments with fixed pitches, such as clarinet, saxophone, flute, piano and organ are recommended. Some instruments produce strong vibration that can be felt on the lips, on the chest or by touching them. Percussion instruments, particularly the bass drum, are great producers of vibration and can therefore provide a very tactile experience. On the other hand, whenever the student is still having difficulties sensing vibrations, instrument selection should include one that is capable of producing sustained rather than percussive sounds, as these may be easier to perceive via residual hearing. The xylophone, with its clear and short sounds, is considered one of the easiest instrument to be perceived by the cochlear implanted child. For further details about the instrument selection for a deaf child, see Hash. Singing activities are also strongly recommended for these children. Cochlear implanted children are generally able to sing familiar songs from memory, though their performance is significantly poorer than in children with normal hearing on almost all pitch-based assessment of singing.

Musical involvement can help a child to develop a positive self-image with opportunities for self-expression and can improve social interactions. Moreover, music can serve as motivational tool for positive behavior and can relieve the tension and struggle that some children experience during language training. The music classroom can play an important role in promoting acceptance and understanding. Musical activity can aid in breaking down any social barriers, thus helping to diminish misconceptions and fear related to hearing loss.
Darrow affirms that almost any aural concept can be visually reinforced. The use of Windows Media Player visuals has been recommended because of their colourful representation of music elements such as rhythm, tempo, and melodic direction. In fact, visual representation of music can help to clarify what children perceive. Moreover, body rhythms can be implemented to symbolise rhythmic structure. Pitch can also be illustrated using the body. For example, younger students can crouch down for low notes and stand on their tip-toes with arms above their heads for higher notes. It has been found that music combined with speech therapy can have positive effects on the development of both good listening habits and auditory skills, and on the development of the suprasegmental elements of language, auditory figure-ground discrimination, sequential memory, voice quality and rhythm of speech. Nevertheless, it should be noted that only studies that carried out a long and intensive musical training with deaf children were able to demonstrate a significant benefit on language perception and productions. For example, Rouchette et al. used training that lasted from 1.5 to 4 years conducted by music teachers with a consolidated experience. In contrast, shorter training carried out by parents or caregivers failed to demonstrated significant positive results. Training benefits were evaluated by using the instrument “Sound in Hands” (Fig. 5). Evaluation included four aspects of auditory perception: discrimination, identification, auditory scene analysis and auditory working memory. In conclusion, it is still debatable whether music training might have a benefit on language perception and production in deaf children. On the other hand, there is a general agreement that musical involvement can help a child to develop a positive self-image with opportunities for self-expression and can improve social interactions. Moreover, hard of hearing children may enjoy music and motivated students are capable of learning to play an instrument to at least an intermediate level.

Neurofibromatosis 2. Hearing-related management strategies

Neurofibromatosis 2 (NF2) is a genetic disease (autosomal dominant) with a variable expression due to the different kinds of mutations, mosaicism being the less serious condition. It involves benign tumours of the central nervous system, schwannoma on nerves, or meningiomas. Other tumours are glioma, ependymoma and posterior subcapsular lenticular opacity. Schwannomas on the nerves involve the unavoidable loss of function of the nerve of origin. The incidence is about 1 new case/year/over 100,000 inhabitants. The mutations are on chromosome 22 in a protein named merlin, which acts as a growth factor regulating (inhibiting) growth. The crucial aspect of the management of NF2 cases is both the decision of what to do and, not less important, when to do something, in the frame of a balance between the natural history of the disease and the consequences of active therapy. The goal of therapy cannot be the cure of the disease, but the setting of pro-active therapy to improve quality of life and prevent the early fate of the disease. When proactive therapy is not successful, functional rehabilitation is feasible, provided early therapy is performed. The role of radiotherapy is limited, for the young age of the patient, the low success of long-term preservation of function and the risk of radio-induced tumours. Clinical observation, radiology and genetics support the diagnosis. The disease is evident in 20% of cases before 15 years with the bilateral schwannoma, the majority of cases after 18 years presentation. The new frontiers in the management of NF2 patient account for: 1) the awareness of the importance of early-stage surgery conceived as functional surgery; and 2) the possibility of rehabilitation, especially of the VIII cranial nerve. The most frequent condition in NF2 is bilateral acoustic schwannoma. This involves a relentless growth of the tumour and an unavoidable loss of hearing over the years, which may be progressive or sudden but is the functional endpoint. Tumour growth in NF2 schwannoma is more aggressive and rapid than in sporadic schwannoma. The natural history of the tumour is also more associated with facial palsy than in sporadic schwannoma. The treatment involves two different attitudes: a “conservative” attitude, which means watchful observation of tumour growth, in which treatment is delayed until function is lost (hearing) and tumour growth is no more tolerated due to size and impending risk of brain compression. When surgery is performed, the size of tumour is such to put facial nerve preservation at risk, not differently from what is the rule in the sporadic tumour. Late surgery with a large tumour prevents the possibility of hearing preservation (which is feasible and advisable only at a very early stage of tumour,) and of the cochlear nerve (which may anatomically be preserved only in small-medium size tumours and its possibility of
functioning with a cochlear implant seems to be inversely related to the preoperative loss of hearing). The advantage of this “conservative” attitude is to leave natural function to patients (hearing and facial nerve) as long as this is possible. The consequences of a delayed surgical treatment are higher intraoperative surgical risks, higher morbidity on the facial nerve and no possibility of hearing preservation/hearing rehabilitation with cochlear implant. Why should we adopt a conservative strategy, which prevents any possibility of preservation/rehabilitation of function? The answer is in the complexity of the disease, where every choice pays a price and has to be balanced very carefully. Sometimes it may be reasonable, for severe NF2 patients, to leave hearing functions intact (on one side at least) as long as this is feasible in the so-called crucial years, when education takes its course and postpone the problem of the management of bilateral acoustic neuroma at a later age. It is evident that this “conservative” attitude, though the most adopted till the 2000’s, has limited value nowadays, or rather it is still an option but has to be balanced in the frame of a more updated programme of management of the NF2 patient. The “proactive” attitude involves an early therapy at an early stage tumour. When good function is still present (hearing) it may be preserved with hearing preservation surgery and, if not, may be rehabilitated with cochlear implant.

In our experience in sporadic and NF2 acoustic neuromas, we observed better results in hearing rehabilitation with cochlear implant when: 1) the tumour was small and the cochlear nerve did not suffer longtime from the presence of tumour; 2) hearing was preoperatively good and a functioning cochlear nerve could be preserved. The rationale of this proactive surgery is not to rehabilitate function straightforward, but to cure the disease at an early stage with the attempt to preserve natural hearing in the best preoperative conditions and rehabilitate it only in case of failure.

We summarise our guidelines in Table I for sporadic tumours.

In NF2 patients, the choice is more difficult and should be balanced in the frame of the severity of the disease and the expectations of the patient and family.

Some considerations are preliminary to any decision-making process in the NF2 patient. A multidisciplinary nature of the approach (neuro-otologist, neurosurgery, genetics, radiotherapy, oncologist); the high rates of success of hearing preservation surgery in sporadic acoustic neuraoma are probably less reproducible in the NF2 patient. The inexorable growth, the multilobular pattern of presentation of the tumour relate to more aggressive involvement of the cochlear nerve and, to a lesser extent, of the facial nerve; bilateral acoustic neuroma is often not an isolated condition, but in the NF2 patient it is associated with other sites as meningoima, schwannoma, gliomas. Surgery may involve higher morbidity due to the presence of other adjacent tumours (i.e. lower posterior fossa, jugular foramen, foramen magnum) that may affect the function of other cranial nerves and the CSF pathways; hearing rehabilitation with ABI, though always feasible, should be the last option after any attempt of hearing preservation/hearing rehabilitation with cochlear implant. Similarly, good facial nerve preservation should be the goal in small-medium size tumours. When not feasible, intraoperative reconstruction of the facial nerve with a graft should be the option.

In conclusion, the new trend in NF2 management involves proactive therapy in the attempt to preserve function or rehabilitate it in case of failure. The attitude of leaving the disease at its fate leads to the unavoidable condition where it is too late to spare function or rehabilitate it. The crucial step of when active therapy should begin to interfere with the natural course of the disease is the main aspect of any choice, as well

as the awareness of the updated surgical procedures of sparing function and rehabilitate it, such as in bilateral schwannoma. When the tumours affect the mixed nerves (i.e. in the jugular foramen, IX-XII cranial nerves), preservation or surgical rehabilitation of function is, at present, still not feasible.

Conclusions
Rehabilitation programs for paediatric patients with disorders of voice, speech and language, communication and hearing, deglutition and breathing are not widely available in either hospital settings or in long-term care facilities. In most countries, the number of physicians and technicians is still inadequate. The goal for the future will be establishment of highly specialised third level centres, where multidisciplinary teams dedicated to paediatric patients can collaborate.

**Spinal accessory nerve preservation in modified neck dissections: surgical and functional outcomes**

Preservazione del nervo accessorio spinale nelle dissezioni del collo: outcomes chirurgici e funzionali

V. POPOVSKI1, A. BENEDETTI1, D. POPOVIC-MONEVSKA1, A. GRCEV1, A. STAMATOSKI1, J. ZHIVADINOVIK2

**SUMMARY**

The spinal accessory nerve (SAN) or XI cranial nerve is frequently encountered during neck surgery, and as such is at risk of iatrogenic injury, resulting in “shoulder syndrome”. Modified neck dissection (MND) with preservation of the SAN is based on desire to minimise the functional deformity associated with section of the eleventh nerve. The aim of this study was to analyse the intra-operative variations of the spinal accessory nerve pathway and to evaluate shoulder dysfunction postoperatively. The cross-sectional demonstration analysis was created through the medical records retrospectively of 165 consecutive patients who underwent neck dissections at our institution in the past 5 years with attention to ultrasound and MRI preoperative findings, type of neck dissection, type of identification and dissection of SAN, postoperative morbidity and survival rate. The safest identification of SAN is in the posterior neck triangle where it may be recognised exiting from the posterior border of the sternocleidomastoid muscle (SCM) at Erb’s point. For exact preoperative planning, ultrasound and MRI are superior to determine the position of the eleventh nerve. The mean distance between the greater auricular point and the SAN was 0.90 cm. Average length of the trunk from Erb’s point until the penetration in the trapezius muscle was around 5.1 cm, ranging from 4.8 to 5.4 cm. The diversity in the course from the posterior border of the SCM and posterior neck triangle was confirmed in 9 cases (15%), predominantly at the level of entering the posterior neck triangle. The frequency of postoperative morbidity of SAN was 46.7% for radical neck dissections, 42.5% for selective neck dissections and 25% for MND. For each separate type of dissection, different subtypes were included. Identification of the SAN over established landmarks is unconditionally reliant on the exact preoperative mapping of the nerve with imaging diagnostics. MND has similar regional control rates to more comprehensive operations in appropriately selected patients and significantly reduces the risk of functional disability.

**KEY WORDS:** Posterior neck triangle • Spinal accessory nerve • Neck metastases • Modified neck dissection • Shoulder function

**RIASSUNTO**

Durante la chirurgia del collo, ci si imbatte frequentemente nel nervo accessorio spinale (SAN) o XI nervo cranico che, pertanto, è a rischio di lesione iatrogena con conseguente “sindrome della spalla”. La dissezione del collo modificata con preservazione del SAN è basata sull’intento di minimizzare le deformità funzionali causate dalla sezione dell’undicesimo nervo. L’obiettivo di questo studio è quello di descrivere le varianti intraoperatorie del nervo accessorio spinale e valutare la disfunzione della spalla nel postoperatorio. Lo studio osservazionale trasversale è stato creato analizzando retrospettivamente 165 pazienti consecutivi che sono stati sottoposti a dissezione del collo presso il nostro istituto negli ultimi 5 anni, ponendo particolare attenzione ai reperti preoperatori derivanti da ecografia e risonanza magnetica, al tipo di dissezione del collo, al tipo di identificazione e dissezione del SAN, ai dati postoperatori di morbidità e sopravvenienza. La più sicura identificazione del SAN avviene nel triangolo posteriore del collo, dove potrebbe essere riconosciuto in quanto emerge dal margine posteriore del muscolo sternocleidomastoideo, a livello del cosiddetto punto di Erb. Per un corretto planning preoperatorio, ecografia e risonanza magnetica sono superiori nel determinare l’esatta posizione dell’undicesimo nervo cranico. La distanza media tra il nervo grande auricolare e il SAN è stata di circa 0,90 cm. La lunghezza media del tronco nervoso dal punto di Erb fino al punto in cui esso penetra nel muscolo trapezio è stata di circa 5,1 cm, con un range da 4,8 e 5,4 cm. La diversità nel decorso dal bordo posteriore dello muscolo sternocleidomastoideo attraverso il triangolo posteriore del collo è stata riscontrata in 9 casi (15%), soprattutto a livello dell’ingresso nel triangolo posteriore del collo. La frequenza di lesione postoperatoria del SAN è stata del 46,7% per le dissezioni radicali del collo, del 42,5% per le dissezioni selettive, e del 25% per le dissezioni modificate. Per ciascun tipo di svuotamento, sono stati inclusi differenti sottoinsiemi. L’identificazione del SAN, step fondamentale nella chirurgia del collo, è assolutamente dipendente da un corretto studio preoperatorio attraverso la diagnosi per immagini. La dissezione del collo modificata ha percentuali di controllo regionale simili a quelle di operazioni più demolitive in pazienti accuratamente selezionati, e riduce significativamente il rischio di disturbi funzionali.

**PAROLE CHIAVE:** Triangolo posteriore del collo • Nervo accessorio spinale • Metastasi cervicali • Dissezione del collo modificata • Funzione della spalla
Introduction

While radical neck dissection (RND) had a principal role in the treatment of cervical neck metastasis for many years, the oncological requirement for RND became disputable upon the definition of “shoulder syndrome” in the second half of the last century. Consequently, modified radical neck dissection (mRND) with preservation of the spinal accessory nerve (SAN) and removal of lymphatic tissues with similar oncological results was described. However, identification of the spinal accessory nerve even in the correct anatomical position is not always easy during different types of neck dissections. The surgical anatomy of the spinal accessory nerve has been properly acknowledged in the literature with evidence of significant variations. The eleventh cranial nerve topography consists of two parts, a cranial part and a main cervical part. The nerve descends in the neck through jugular foramen and near the jugular vein exits in the posterior neck triangle and supplies the sternocleidomastoid and trapezius muscles. These muscles have the functions of: elevation of the shoulder by the trapezius, rotation and tilting of the head toward and away from the side of the contracting sternocleidomastoid muscle and flexion of the neck by both sternocleidomastoid muscles. This cervical part is associated by motor or sensory contributions from the upper cervical nerves. These functions are decreased or absent of weakness or paralysis. When the lesion is nuclear or infranuclear, there is associated muscle atrophy and fasciculations.

On the other hand, neck dissection is a principal technique for diagnosis (staging) and treatment of cervical lymph node metastasis in patients with head and neck cancer. In modified neck dissections when indications are raised, a very important part is preservation of the spinal accessory nerve, together with internal jugular vein and sternocleidomastoid muscle. The pain and dysfunction associated with loss of innervation on spinal accessory nerve has motivated surgeons to modify the classic neck dissection. The modified neck dissection with preservation of the spinal accessory nerve is based on desire to minimise the functional deformity associated with section of that nerve, combined with the recognition that in many situations the nerve intimately involved in the neck disease and its preservation does not compromise the oncological effectiveness of the more limited procedure.

Since the introduction of functional neck dissection, various modifications have been made to reduce the adverse effects of radical neck dissection and have contributed to improving the quality of life and preventing permanent sequelae and medico-legal actions following neck dissection. Proficient knowledge of posterior neck anatomy is crucial to avoid its accidental injury during selective or modified neck dissection in almost any extensive surgery of the posterior neck. Reasonable speed and safety in identifying and preserving important anatomical structures are of fundamental importance, and for this type of neck dissection special attention must be paid to refined identification of the spinal accessory nerve. The aim of this study was to analyse the intra-operative variations of the spinal accessory nerve pathway and to evaluate shoulder dysfunction postoperatively.

Materials and methods

A comparative, prospective study of surgical alterations of the spinal accessory nerve and trapezius muscle function of patients who underwent distinctive neck surgery was performed. This study was done not only to document the indispensability of the trapezius muscle to shoulder-strap stability, but also to clarify the role of eleventh cranial nerve preservation. The cross-sectional demonstration analysis was created on clinical material from the Clinic for Maxillofacial Surgery in Skopje, where in the last five-year period, unilateral neck dissections were performed in 165 patients, of whom 59 were treated with radical neck dissection, 20 with modified neck dissection and in 86 cases with adequate type of selective neck dissection. Neck dissection with a curative intent was done in 80 patients with squamous cell carcinoma of the upper aerodigestive tract (naso- and oro-pharynx), in 26 patients with skin squamous cell carcinoma, 17 with salivary gland carcinoma, 11 with malignant melanoma and 31 with hidden primary.

We evaluated clinical records for this study in 20 patients with modified neck dissection (type I, II, III) and 40 patients with selective neck dissections (supra-omohyoid, lateral, posterolateral, anterior compartment), comparing preoperative diagnostic work-up, intraoperative findings and relationship of the dissected and preserved eleventh nerve with tumour masses and postoperative complications. T1-weighted high-resolution isotropic volume examination for the preoperative assessment of head and neck cancer, by comparison with spin-echo, T1-weighted sequences and the pathology specimen. Bland-Altman plots to assess measurement agreement, Shoulder Disability Questionnaire (SDQ), and Constant-Murley Shoulder Score were used to detect differences between the normal and abnormal sides. In selected cases, an intraoperative mapping study was done to obtain the exact anatomical data by drawing the exposed accessory nerve in life size during the modified neck dissection. All measurements were made at the end of the procedure by using a Vernier Caliper with 1/64” in classic anatomic position of the supine body with turned the patient’s head about 45°. After the completeness of lymph node and metastases removal from the posterior neck triangle, evaluation was performed over extensive exposure of the spinal accessory nerve. Towards the end of the dissection, the correct location of the nerve was corroborated by enlarging the exposure to confirm the position and integrity of the preserved nerve.

Clinical, electrophysiological and neurologic evaluations of the trapezius and sternocleidomastoid muscles (fibril-
lation and positive sharp waves) were performed at 3 months postoperatively for 20 mRND and 40 SND patients, and 6 months postoperatively only for 20 mRND patients. Stimulus intensity and duration were increased until the maximal amplitude level was achieved. Latency was defined as the time from the application of stimulus to the initial negative deflection of the amplitude. Statistical analysis was performed using IBM SPSS statistics ver. 20. P values lower than 0.05 were considered significant.

Results

Intraoperatively we found significant variances in the positioning of the spinal accessory nerve. Particular attention was paid to identification of spinal accessory nerve positioning and its relationship with the internal jugular vein. Our findings confirmed that the spinal accessory nerve almost always crosses the internal jugular vein anteriorly in the upper neck, with exclusion in 4 cases (6.7%), with posterior crossing at the level of posterior belly of the digastic muscle and one case with rare anomaly where accessory nerve passing through the fenestrated internal jugular vein was observed. In 20 cases we measured the distance from the jugular foramen (skull base) to crossing of internal jugular vein with a mean value of 2.34 cm (ranging from 2.27 to 2.43 cm) (Fig.1).

The diversity in the course from the posterior border of the sternocleidomastoid muscle and posterior neck triangle were confirmed in 9 cases (15%), predominantly at the level of entering the posterior neck triangle. The hypoplastic nerve was apparent in 8.3% (5 cases), generally after removal of neck masses with greater proportions. Hyperplastic nerve was evident in only 3.3% (2 cases). In almost every case we found that the spinal accessory nerve had a typical coiled appearance in its course through the posterior cervical triangle of the neck (Fig. 2). The mean distance between the greater auricular point and the spinal accessory nerve was 0.90 cm. Average length of the trunk from Erb’s point until the penetration in the trapezius muscle was around 5.1 cm, ranging from 4.8 to 5.4 cm. The most significant elongation was found in cases after meticulouss preparation of spinal accessory nerve – usually after complete removal of neck metastases at levels III - V. There were 4-8 lymph nodes in the spinal accessory nerve chain (Fig. 3).

Measurements of abduction and electromyographic measurements (monopolar needle electrode) of the study group (modified radical neck dissection) in 3 and 6 months postoperatively were found to be superior to those of the control group (selective neck dissection), although the difference between groups was not significant (Table I) Damage to the motor unit averagely recorded at ranges between 320-540 mV. The mean number of dissected lymph nodes was significantly higher in the study group than in the control group. The frequency of postoperative morbidity of the spinal accessory nerve was the highest in radical neck dissections (46.7%) in 28 cases. There was a reduced function in 17 cases with selective neck dissection (42.5%) comparing to preoperative values, while shoulder drop and scapular winging was confirmed in only 5 cases (25%) of modified neck dissection.

The most significant was correlation after radical neck dissection and modified neck dissection including levels IIb and V (Fig. 4). Statistical significance was obtained between shoulder pain score and EMG fibrillation or positive sharp wave score (p < 0.05). The Shoulder Disability

The arm abduction test was with score of 4.3 in properly treated cases with preservation of SAN.

Five patients with history of adhesive capsulitis were enrolled who had higher EMG ratios of the upper trapezius to lower trapezius during arm elevation.

Patients who underwent supraomohyoid selective neck dissection that involved minimal dissection of the spinal accessory nerve had minimal loss of shoulder function and usually, normal electromyograms in 3 months that documented less injury to the spinal accessory nerve. Again, these patients had improvement with the time. No patient had recurrence of neck disease during at least 3, 6 and 12 months of follow up.

Discussion

The main therapeutic dilemma for the therapy of metastatic carcinoma from head and neck malignancy remains the choice of the type of neck dissection. The probability of metastases to the neck from various sites in the upper aerodigestive tract has been outlined, so there are data from much of the literature on the technique and indications for functional modifications of the classical radical neck dissection. Conley and Schuller confirmed a large percentage of metastases (42%) in close proximity to the spinal accessory nerve where it comes to lie near the internal jugular vein. Ballantyne, Shah and Bocca’s group gave strong support to MRND emphasising that in many situations the spinal accessory nerve is not intimately involved in neck disease and its preservation does not comprise the oncologic effectiveness of the more limited procedure. These and other investigations have designated the introduction of modified neck dissections.

Beneficial surgical intervention in case of posterior neck metastases depends on suitable exposure and preservation of the spinal accessory nerve. This induces a consistent understanding of the anatomy of the posterior neck triangle for performing surgery safely, including the sufficient knowledge of extracranial anatomy of spinal accessory nerve variations.

Patten and Hillei indicated that adhesive capsulitis is a principal component of XI nerve syndrome that can significantly compound the morbidity of a neck dissection even when the accessory nerve recovers.
Our findings support results in the literature that the spinal accessory nerve is located anterior to the internal jugular vein in the majority of the cases, although it is imperative for the surgeon to be mindful to anatomic variability and possible posterior crossing of the internal jugular vein by the spinal accessory nerve in the neck to avoid injury to the internal jugular vein during the dissection of the nerve. Since the great auricular nerve (Erb’s point) represents a constantly identifiable landmark, it allows simple and reliable identification of the course of the spinal accessory nerve. Across the posterior triangle, the nerve was running superficially with either straight (78%) or coiled (22%) pathway. The accessory nerve and the phrenic nerve were similar in terms of anatomic evidence and number of motor nerve fibres. On ultrasound evaluation, the accessory nerve exited the posterior border of sternocleidomastoid at a mean of 6.5 (5.0-8.5) cm below the mastoid process and penetrated the anterior border of trapezius 5.5 (3.0-7.0) cm above the clavicle with mean caliber of 0.75 ± 0.10 mm. The most common complication of neck dissection is shoulder pain and dysfunction due to manipulation of the spinal accessory nerve, resulting in trapezius muscle atrophy mainly in procedures involving the posterior neck triangle. Lee et al. 20 showed that 22 of 25 (88%) patients had shoulder pain, but that the average pain score was low (2.3 ± 1.3).

Kuntz and Weymuller 21 reported that the modified radical neck dissection group of patients reported greater shoulder disability at 6 months compared with the selective neck dissections group, but at 12 months there was no difference between the two groups. Giordano et al. 22 analysed shoulder function after selective and superselective neck dissections, and the subjective test showed no significant differences between the two groups even when sublevel IIB is spared. The findings of Cheng et al. 23 in their prospective study with subjective evaluation of shoulder pain and objective evaluation of shoulder muscle strength suggested that patients who underwent selective neck dissection had the least damage to spinal accessory nerve function and the least shoulder disability after neck dissection. Cappiello et al. 24 compare the results of clinical and electrophysiological investigations of shoulder function in patients affected by head and neck carcinoma, and a high number of abnormalities was found on electrophysiological testing, only a limited number of patients, mostly in group B (received a selective neck dissection involving clearance of levels II-V), displayed shoulder function disability affecting daily activities.

In a study by Remmler et al. 25 modified nerve sparing dissections were followed on the average by a significant, but temporary and reversible phase of shoulder dysfunction. By comparison, radical neck dissection is followed by profound and permanent trapezius muscle weakness and denervation 25.

Birinci et al. 26 carried out a prospective, double-blind clinical trial where shoulder function deterioration was significantly less for patients with insignificant intraoperative neuromonitoring changes than in patients with significant intraoperative neuromonitoring changes (P < 0.05).

Chepeha et al. 27 concluded that patients receiving modified radical neck dissection had significantly worse shoulder function than patients with selective neck dissection (p = 0.0007).

Van Wilgen et al. 28 reported that after modified radical neck dissection 33.3% of patients experienced shoulder complaints; after posterior-lateral neck dissection 66.7% and after supraomohyoid neck dissection 20% of the patients experienced shoulder complaints. Wilgen et al. 28 indicated that the type of neck dissection was significantly (P < 0.001) related to shoulder complaints.

Selcuk et al. 29 showed that in patients who underwent anterolateral neck dissection, the goniometric results were better than with the functional neck dissection. Macaluso et al. 30 reported that early detection of spinal accessory nerve injuries can be improved through EMG testing.

According to Svenberg et al. 31, an important landmark in the neck is to detect the branches from cervical plexus to potentially provide the surgeon with important intraoperative nerve identification and monitoring following surgical injury to the SAN.

Our study indicates that there may be functional disability associated with any type of neck dissection in which the spinal accessory is dissected and placed in some degree of traction. The finding of significantly lower risk of functional disability in modified neck dissections, and confirmation that the modified neck dissection is as effective as the radical neck dissection for controlling neck disease, extends the indications for modified or selective neck dissections as a more logical approach to surgical treatment.

of cervical neck disease. If there is no functional advantage, all other arguments for modified neck dissections become inappropriate.

We proposed that adhesive capsulitis is a principal component of XI nerve syndrome that can significantly compound the morbidity of a neck dissection even when the accessory nerve recovers. The subsequent development of adhesive capsulitis in our patients disappeared after 2 months postoperatively.

The results of this study show that, on average, neck dissection patients with the spinal accessory nerve preserved have less pain in their shoulders, less functional disability and stronger results on physical examination than those with the spinal accessory nerve sacrificed without any difference in local control and survival. This is of importance because the spinal accessory nerve sacrificed without any difference in the neck and accessory nerve palsy or adhesive capsulitis?

Conclusions
We can validate that the spinal accessory nerve injury is potentially preventable in most cases of neck surgery. Surface anatomical landmarks are not always a reliable guide to the position and course of the nerve in the posterior triangle. Within modified neck dissections, identification of spinal accessory nerve over established landmarks is unconditionally reliant on the exact preoperative mapping of the nerve with imaging diagnostics, but the sophisticated further eleventh nerve dissection and preservation depends on the inclusive surgical knowledge. Modified neck dissection has similar regional control rates to more comprehensive operations in appropriately selected patients and significantly reduces the risk of functional disability.

SUMMARY
Temporary and permanent facial nerve dysfunctions can be observed after parotidectomy for benign and malignant lesions. Intraoperative nerve monitoring is a recognised tool for the preservation of the nerve, while the efficacy of the operative microscope has been rarely stated. The authors report their experience on 198 consecutive parotidectomies performed on 196 patients with the aid of the operative microscope and intraoperative nerve monitoring. 145 parotidectomies were performed for benign lesions and 53 for malignancies. Thirteen patients treated for benign tumours experienced temporary (11 cases) or permanent facial palsy (2 cases, both of House-Brackmann grade II). Ten patients with malignant tumour presented with preoperative facial nerve weakness that did not improve after treatment. Five and 6 patients with malignant lesion without preoperative facial nerve deficit experienced postoperative temporary and permanent weakness respectively (the sacrifice of a branch of the nerve was decided intraoperatively in 2 cases). Long-term facial nerve weakness after parotidectomy for lesions not directly involving or originating from the facial nerve (n = 185) was 2.7%. Patients treated for benign tumours of the extra facial portion of the gland without inflammatory behaviour (n = 91) had 4.4% facial nerve temporary weakness rate and no permanent palsy. The combined use of the operative microscope and intraoperative nerve monitoring seems to guarantee facial nerve preservation during parotidectomy.

KEY WORDS: Parotid tumours • Facial weakness • Intraoperative nerve monitoring • Microscope-assisted parotidectomy • Salivary glands

RIASSUNTO
I pazienti sottoposti ad intervento chirurgico di parotidectomia per lesioni benigne e maligne possono presentare disfunzioni temporanee o permanenti del nervo facciale. Il monitoraggio intraoperatorio della motilità facciale è uno strumento ampiamente riconosciuto per la sua utilità nella conservazione del nervo, mentre l’efficacia del microscopio operatorio è stata raramente discusso. I pazienti sottoposti ad intervento chirurgico per lesioni benigne e maligne possono subire disfunzioni del nervo facciale. L’uso combinato del microscopio operatorio e del monitoraggio intraoperatorio del nervo facciale è stato raramente discusso. Gli autori riportano la loro esperienza su 198 parotidectomie consecutive eseguite su 196 pazienti con l’ausilio del microscopio operatorio e del monitoraggio intraoperatorio del nervo facciale. Centoquarantacinque pazienti hanno sottoposto ad intervento chirurgico per lesioni benigne e maligne. Sedici pazienti operati per lesioni benigne hanno presentato un deficit della funzionalità del nervo facciale: 11 hanno sofferto di paralisi temporanea e 2 di paralisi permanente (entrambe di secondo grado). Dieci pazienti affetti da patologia maligna hanno presentato un deficit della funzionalità del nervo facciale: 3 hanno sofferto di paralisi temporanea e 7 di paralisi permanente. La combinazione dell’uso del microscopio operatorio e del monitoraggio intraoperatorio del nervo facciale sembra garantire la conservazione del nervo facciale nei pazienti sottoposti a parotidectomia.

Acta Otorhinolaryngol Ital 2017;37:375-386
Introduction

Salivary gland neoplasms represent 3% of all head and neck tumours, the majority of which originate from the parotid. Surgical treatment of parotid neoplasms is focused on complete removal of the tumour together with the extra-petrosal dissection of the facial nerve. Although parotidectomy is a well-known and safe procedure if correctly performed, immediate postoperative facial nerve weakness may occur in 10% to 40% of patients treated for a benign neoplasm, whereas permanent postoperative facial weakness has been described in 1% to 7.1% of patients. Malignant lesions are generally related to a higher rate of postoperative palsy.

Intraoperative nerve monitoring (NIM) has been associated with a lower risk of immediate postoperative facial nerve palsy in primary cases of parotidectomy, while the efficacy of the operative microscope during the parotidectomy has been rarely evaluated. The authors report their experience on the surgical management of parotid gland tumours with microscope assisted parotidectomy (MAP) combined with NIM, focusing on postoperative facial nerve function and clinical/oncologic outcomes according to histology.

Materials and methods

This is a prospective study involving a consecutive cohort of 196 patients treated at our Department with MAP coupled with NIM from November 2010 to January 2016. Medical history was collected before admission. High-resolution ultrasonography (US), computerised tomography (CT), magnetic resonance imaging (MRI) and fine needle aspiration cytology (FNAC) were used for preoperative evaluation, although not always together. Facial nerve function was evaluated preoperatively, on the first day after surgery, after one month and at least at three months after surgery using the House-Brackmann scale completed with the description of the function of all the facial nerve branches (frontal, zygomatic, buccal, mandibular). Patients underwent superficial (removal of all the parotid tissue above the facial nerve) or total parotidectomy (extended to all parotid tissue including the deep lobe of the gland), according to the extension of the tumour. We never performed enucleations or extra-capular dissections. Neck dissection (levels II-V) and adjuvant therapies were performed in case of malignant lesions, according to the Oncology Guidelines approved by our Institutional Review Board. Facial nerve dissection was always performed coupling the intraoperative microscope (ZEISS S7, focal length 250 mm) with NIM (Medtronic NIM Response® 3.0-4 channels). Typical parameters used at our institution are: stimulus intensity of 0.5-0.7 mA, duration of the stimulus of 100 μsec, rate of the stimuli of 4 bursts/sec and event threshold of 100 μV. Antibiotic prophylaxis (ceftriaxone 1 g IV/day) was given at least 30 min preoperatively; corticosteroids (dexamethasone, 4 mg/day for 7 days) were used when immediate postoperative facial nerve weakness was present. Patients were reviewed during this study for the purpose of facial nerve dysfunction and oncologic outcome as well as for development of symptomatic Frey’s syndrome and numbness of the pinna following the sectioning of the great auricular nerve (GAN). This study also considered the correlation between facial nerve dysfunction, histology and surgical complexity (total parotidectomy and superficial parotidectomy, benign neoplasms of the superficial and deep lobe, inflammatory lesions of the superficial and deep lobe, facial nerve schwannoma, primitive malignant tumours of the superficial and deep lobe, lymphomas, normal parotid gland removed during management of skin malignant neoplasms, metastatic tumours of the parotid without skin infiltration or preoperative facial nerve involvement, metastatic tumours of the parotid with skin infiltration or preoperative facial nerve involvement). Patients with a diagnosis of lymphoma were referred for long-term oncologic follow-up to the Department of Onco-haematology with autonomous follow-up. Survival time was assessed from the date of surgery to the date of the last follow-up visit. 5-year overall survival (OS) and disease-specific survival (DSS) rates were calculated using the Kaplan-Meier method. The statistical significance of the different patient populations was tested with the chi-square test, considering significance when p was less than 0.05.

Results

During the period of the study, 198 parotidectomies were performed on 97 men and 99 women (sex ratio M/F of 0.98, mean age 56.1 years, range 15-88). The procedure was performed on the right side in 95 patients, on the left side in 99 patients and bilateral in 2 cases (1 patient presented a primary benign neoplasm of both the parotid glands and 1 patient underwent bilateral parotidectomy for suspicious bilateral metastasis of skin malignancy of the scalp). 145 parotidectomies (73.2%) were performed for benign lesions and 53 (26.8%) for malignant lesions (Table I). 169 patients were evaluated for a chronic swelling of a parotid mass previously confirmed with US, 6 patients were treated for local recurrence after parotidectomy for benign lesion performed elsewhere, 11 patients were treated for possible parotid involvement of cutaneous tumours, and 10 patients presented with an advanced malignant neoplasm with clinical involvement of the parotid area. 143 patients (73%) were preoperatively evaluated with MRI with contrast medium; 53 patients (27%) were evaluated only with CT with contrast medium (28 patients affected by malignant lesions were investigated only with CT). MRI (41.2%) allowed a preoperative diagnosis in 59 cases: 70.9% (44/62) of MRI for pleomor-

1. 1 patient underwent bilateral parotidectomy for bilateral Warthin’s tumour
2. Facial nerve neoplastic infiltration was evident preoperatively in 7 cases.
3. Facial nerve neoplastic infiltration was evident preoperatively in 1 case.
4. Facial nerve neoplastic infiltration was evident preoperatively in 1 case.
5. 1 patient was submitted to bilateral parotidectomy for suspicious bilateral metastasis of squamous cell carcinoma; histology revealed the carcinoma in only one parotid gland.
6. 1 patient was submitted to parotidectomy with radical neck dissection for head and neck melanoma; histology did not reveal the melanoma in the parotid gland.
7. A facial nerve deficit was preoperatively due to the neoplastic involvement of the nerve from the zygomatic skin malignancy in 1 case.
phic adenomas allowed pre-operative diagnosis, while only 13.3% (4/30) of MRI were reliable in pre-operative diagnosis of Warthin’s tumour. CT and/or MRI allowed preoperative diagnosis of malignant lesion of the parotid in 18 cases (34%), in 24 cases (45.3%) it confirmed the parotid lesion but could not predict the benign or malignant nature, and was negative in 11 cases (20.7%) whose definitive histological analysis confirmed the presence of carcinoma. FNAC was performed in 37 patients (18.9%), and was predictive in 22/37 lesions (accuracy of 59.5%). FNAC diagnosis of pleomorphic adenoma was predictive in 100% of cases (n = 9), while FNAC was diagnostic in 50% of cases of Warthin’s tumour (2/4 patients). Patients with a cytological diagnosis of benign tumour of the parotid lesion but could not predict the benign or malignant nature, and was negative in 11 cases (20.7%) whose definitive histological analysis confirmed the presence of carcinoma. FNAC was performed in 37 patients (18.9%), and was predictive in 22/37 lesions (accuracy of 59.5%). FNAC diagnosis of pleomorphic adenoma was predictive in 100% of cases (n = 9), while FNAC was diagnostic in 50% of cases of Warthin’s tumour (2/4 patients). Patients with a cytological diagnosis of benign tumour of the parotid (n = 19) was benign in 18 cases, while 1 was malignant. Patients with FNAC suspicious for malignancy (n = 5) underwent neck dissection during the same procedure after intraoperative histological confirmation (4/5 resulted pN+), patients with non-diagnostic FNAC (n = 13) were submitted in 11 cases to parotidectomy alone (definitive diagnosis showed 2 primary malignancies, 1 lymphoma and 8 benign lesions), in 1 case to a delayed neck dissection after histological diagnosis of primitive parotid malignancy, and in 1 case with obvious clinical malignant behaviour, to parotidectomy with neck dissection performed during the same general anaesthesia after intraoperative histological confirmation of the malignant nature of the lesion. Trans-nasal intubation was always performed to avoid the retrograde move of the angle of the mandible due to the oro-tracheal tube, improving the space for nerve identification. A superficial parotidectomy was performed in 140 cases (70.7%) and a total parotidectomy in 58 cases (29.3%). Thirty-eight tumours (19.2%) involved the deep lobe of the parotid gland (28 benign neoplasms, 3 malignant lesions and 7 inflammatory lesions). The sacrifice of single branches of the nerve involved by the tumour was necessary in 13 cases: in 10 patients, the involvement of the nerve was preoperatively obvious, in 2 cases it was evident only intraoperatively (neural invasion was definitively confirmed by histology as shown in Fig. 1) and in 1 case the tumour was originating from the nerve; in 4 cases GAN grafting was performed in the attempt to restore the nerve continuity. Two parotidectomies were performed during management of a head and neck melanoma. In 28 cases the parotidectomy was associated with a selective or modified radical neck dissection, in 3 cases it was associated with the removal of the pinna, and in 8 cases it was widely extended to the facial skin and required a reconstructive procedure (2 pectoralis major pedicled flaps, 2 platysma pedicled flaps, 3 free flaps of rectus abdominis, and 1 forearm free flap). Three patients underwent delayed neck dissection after histological diagnosis of parotid malignancy.

Average operation time for benign lesion was 221 min (range of 120-350). Mean hospitalisation time was 4.3 days (2.4 days for patients submitted to parotidectomy alone and 7.7 days for patients submitted to more invasive procedures). Postoperative complications occurred in 17 patients (Table II). Bleeding always required surgical revision of the haemostasis, while other complications like seroma, salivary fistula and infection were managed by antibiotics and conservative procedures.

Among the benign pathologies (n = 145), 11 showed a temporary (7.6%) and 2 a permanent weakness (1.4%) of the facial nerve. The 11 temporary weaknesses were grade II in 8 cases and grade III in 3 cases, with a mean recovery time of 2.3 months (0.2-6 months); in 3/11 cases the tumour involved the deep lobe of the gland and in 4/11 cases the lesion (inflammatory) presented multiple adherences to the nerve. The 2 permanent palsies were of grade II and involved one single branch of the nerve: the first was observed after total parotidectomy for an inflammatory cystic lesion of the para-pharyngeal portion of the parotid gland adhering to the marginal mandibular branch, and the second after superficial parotidectomy for a schwannoma originating from the zygomatic branch of the facial nerve. Among the malignancies, 10/53 procedures were performed in patients with preoperative facial nerve weakness that did not improve after treatment; patients without preoperative facial nerve deficit experienced a temporary weakness in 5/43 cases (11.6%), while in 6/43 cases (14%) presented a permanent deficit (in 2 cases the palsy was due to the surgical removal of a peripheral branch of the nerve macroscopically involved by the tumour, and in 3 cases it was observed after parotidectomy associated with selective neck dissection). Temporary and permanent facial nerve weakness rates after superficial and total parotidectomy in patients without preoperative deficit were 7.1% (10/140) and 3.6% (5/140)
vs. 12.5% (6/48) and 6.25% (3/48) respectively. Patients treated for benign tumours of the extra-facial portion of the gland without inflammatory behaviour (n = 91) had 4.4% facial nerve temporary weakness rate and no permanent palsy. Patients without preoperative facial weakness undergoing superficial or total parotidectomy associated with neck dissection showed a 11.1% rate (2/18) of definitive deficit of the mandibular branch of the nerve; permanent facial nerve weakness after parotidectomy for benign and malignant lesions not directly involving or originating from the facial nerve was 2.7% (5/185). The degrees and branches involved are detailed in Table III. After surgery, 15 patients treated for malignancy underwent adjuvant radiotherapy (50–60 Gy, associated with chemotherapy in 5 patients). Two patients with melanoma underwent adjuvant chemotherapy.

No recurrences have occurred after surgery for benign lesions to date. Among the malignancies, 46 patients were included in regular oncologic follow-up at our Department; mean follow-up period was 20 months (range of 3 month-5 years). Two patients experienced local recurrence and underwent chemoradiotherapy, 2 patients (1 diagnosis of melanoma and 1 Merkel carcinoma) experienced neck skin relapse and underwent salvage surgery followed by chemotherapy and radiotherapy, respectively, 3 patients experienced distant metastasis and underwent chemotherapy. Thirty-five patients were alive with no evidence of parotid tumour-related disease at the last follow-up, while 5 patients died of disease and 6 patients died for other causes. DSS and OS for the cohort of patients followed-up in our Department (n = 46) were 83% and 70.6%; patients with primary malignancy of the parotid (n = 22) showed DSS and OS of 85.6% and 81.3%; patients with metastatic squamous cell carcinoma involving the parotid (n = 15) showed DSS and OS of 90.9% and 53.8%; patients submitted to parotidectomy for suspicious metastasis of squamous cell carcinoma, but negative at histology (n = 6) presented DSS and OS of 100%; patients with preoperative facial nerve weakness/skin infiltration (n = 10) presented DSS and OS of 85.7% and 45%; patients without preoperative facial nerve weakness/skin infiltration (n = 36) presented DSS and OS of 80.3% and 74.6%; patients with node metastasis (n = 17) presented DSS and OS of 76.4% and 54.3%; patients without node metastasis (n = 29) presented DSS and OS of 87% and 80.4% (Fig. 2).

All patients experienced postoperative auricular numbness; at present (or at the last examination for patients died during the follow-up), 133 patients still report numbness in correspondence of the inferior lobe of the pinna: 44.7% who underwent parotidectomy in 2011, 65.9% of those treated in 2012, 67.5% of those treated in 2013, 90.2% of those treated in 2014 and 97.2% of those treated in 2015. Thirty-five patients experienced a Frey’s syndrome after parotidectomy performed for benign tumour (n = 145). No patients experienced first bite syndrome.

### Discussion

A large variety of benign and malignant tumours can arise from the salivary glands, therefore, when a localised parotid mass is detected, it requires a specific diagnostic work-up focusing on evaluating the risk of malignancy, since it changes the prognosis and the attitude toward the facial nerve. High-resolution US, conventional MRI and CT with contrast medium are commonly used for evaluating parotid masses. We used, when possible, MRI for preoperative evaluation, but in patients previously evaluated with adequate CT scan images, we did not ask for further imaging. Preoperative diagnostic assessment also takes advantage of FNAC, a minimally invasive technique with a recognised role in cytological diagnosis of patients with salivary gland tumours, with reasonable sensitivity and specificity. Nevertheless, the interpretation of FNAC of salivary gland lesions could be a great challenge for cytologists: the material provided by FNAC may contain poor diagnostic elements and there are some rare tumours that can cause confusion. Piccioni et al reported sensitivity and specificity rates of 81% and 99%, respectively, excluding non-diagnostic procedures; however, the analysis of all the procedures of the same study, diagnostic and non-diagnostic, shows an accuracy rate of 77.3% (136 reliable diagnoses in 176 procedures). FNAC has been employed in our Department since 2010, with an accuracy of 59.5%, in preoperative differential diagnosis of benign to malignant neoplasms. The experience of the pathologist is considered fundamental in FNAC. According to the literature, we consider that FNAC contribute to, but cannot substitute overall diagnostic assessment.

We do not use it systematically when clinical and radiologic evaluations appeared enough to diagnose a benign lesion since the FNAC would not have modified the therapeutic approach. In only one patient with definitive histology showing malignancy, non-diagnostic FNAC was considered responsible for a delayed neck dissection. In the presence of a parotid lesion, it is mandatory that complete removal of the tumour is performed in form of enucleation/extra-capsular dissection (the removal of the entire lesion, without sacrifice of parotid tissue) and superficial or total parotidectomy with the complete excision of the gland including the tumour in healthy margins. Parotid dissection is based on the anatomical knowledge of the extra-temporal facial nerve course and its branches. The classic approach to parotidectomy is anterograde from the main trunk of the VII cranial nerve to the peripheral branches. The main trunk of the nerve is identified and isolated where it emerges from the stylo-mastoid foramen, through the three classical landmarks: mastoid tympanic sulcus, the “pointer” and the posterior belly of the digastric muscle. We routinely perform anterograde dissection with superficial or total parotidectomy, but in three cases of voluminous tumour arising from the superficial lobe of the gland with wide contact between the deepest

*The tumour originated from the nerve and required the sacrifice of a minor branch.
**2 procedures required sacrifice of a peripheral branch of the nerve that was directly involved by the neoplasm.
aspect of the tumour and the main trunk of the nerve, we performed a retrograde dissection, starting from the identification of the frontal branch being the most superficial in the close proximity to the incision, and no postoperative facial nerve weakness was observed. Extra-capsular dissection through a standard preauricular approach is reported in the literature, abandoning the concept of formal dissection of the nerve with minimal dissection of parotid tissue. Mantsopoulos et al. suggested that this technique may be applied in cases of a superficially located mobile lesion or in cases of pleomorphic adenoma arising from the pharyngeal portion of the parotid after digastric muscle sectioning (trans cervical approach), while a more radical procedure requiring dissection of the facial nerve and its branches should be reserved only after detection of malignancy in frozen sections of an extra-capsular specimen. He reported a 1.9% rate of postoperative permanent facial palsy after extra-capsular dissection for benign neoplasms of the superficial lobe. We observed a lower incidence of facial palsy (4.4% temporary weakness rate and no permanent palsy) after superficial parotidectomy performed for well-defined benign tumours of the superficial lobe of the parotid gland, and we do not agree with the extra-capsular dissection also on the basis of our personal histological findings of pleomorphic adenomas that lack of a capsule (Fig. 3). Superficial parotidectomy in experienced hands moderately increases surgical time compared to extra-capsular dissection, but we believe that it is rewarding in terms of facial palsy and risk for recurrences, allowing to remove intraparotid lymph nodes, avoiding asymmetry of the parotid region and reducing the chances to leave metachronous Warthin’s tumours. Nevertheless, extra-capsular dissection has to be performed in the majority of tumours of the deep lobe of the parotid, where the glandular parenchyma is very limited or, when the tumour of the superficial lobe is in close contact with the nerve;

Fig. 2. Survival rates according to different risk factors in malignancies.

Fig. 3. H&E: microscopic view (a & b 10X, c & d 20X) of a discontinuous capsule of a pleomorphic adenoma. The removal of the lesion by superficial parotidectomy leaving a border of glandular parenchyma along the tumour allowed complete removal of the lesion.
in these cases a blunt dissection, usually performed by the finger of the surgeon, represents the most frequently performed technique. Spillage of the tumour after an accidently interrupted capsule is indeed the main cause of single or multiple recurrences, while complete removal of the lesion without spillage of the tumour, leaving a boundary of parenchyma along the tumour can be obtained only after the complete visualisation of the facial nerve. Furthermore, the experience of the surgeon arises only from routine careful dissection of the nerve that may be imperative in challenging cases, such as voluminous tumours, recurrences and chronic inflammation. Witt et al. observed a higher tumour recurrence rate after extra-capsular dissection (3%) than after superficial parotidectomy (0.3%) with a $p < 0.05$ 23. Colella et al. also reported lower recurrence rates after total or superficial parotidectomy (0.01% and 0.02% respectively) compared to those reported after extra-capsular/enucleation (0.08%) 24.

On the contrary, Albergotti et al. did not observe difference in tumour recurrence after superficial parotidectomy vs. extra-capsular dissection, with a significantly lower rate of transient facial nerve paresis after extra-capsular dissection and no difference in permanent facial paralysis between the two procedures 25. In the present series we did not observe spillage of the tumour as a consequence of accidental rupture of the capsule, and we did not observe recurrence of benign tumours. Facial nerve injury is the most significant complication of parotidectomy 2. Postoperative facial weakness may be due to the section of the nerve, intraoperative trauma (thermal trauma, compression or stretching), or ischaemia, when neoplasms adhere to the nerve and require a dissection with the sacrifice of the "vasa nervorum". Nerve damage is classified as neurapraxia, axonotmesis, and neurotmesis, largely based on the degree of injury, which ranges from microscopic to macroscopic 26. When the anatomy of the nerve is preserved, the facial deficit should resolve within 12 weeks 27, after this time all deficits could be considered definitive with low chance of regression. House-Brackmann is a common and reproducible tool developed to quantify facial function in six steps from normal (I) to total paralysis (VI). Since it doesn’t fully correlate with facial function of each of the branches 28, in our study we added the description of the function of each single branch, with main attention to the marginal mandibular branch.

Intraoperative facial nerve monitoring is widely used in otology, neurotology, and skull base surgery 2 29 30. The goals of NIM during parotidectomy are the same as those during otology and neurotology: early facial nerve identification, warning the surgeon of unexpected facial nerve stimulation, mapping of the course of the nerve, reduction of mechanical trauma to the nerve and evaluation and prognosis of nerve function at the end of the procedure 31. Facial nerve monitoring is a safe procedure: facial nerve injury due to voluntary overstimulation is almost impossible, since electrically evoked facial nerve responses during electrophysiological facial nerve monitoring are obtained using a safe pulsed facial nerve probe, and the intensity of the stimulus is preoperatively established.

In our protocol, the setting of the stimulation was never greater than 0.7 mA. Other complications may be due to nerve electrodes such as skin infection and bleeding, but these are rare with sterile techniques and proper needle electrode placement and removal. There is a statistically significant reduction in postoperative facial nerve weakness in patients treated with the aid of NIM 2 32, and postoperative facial dysfunction can be presumed intraoperatively by an elevated nerve response (> 0.5 mA) 32.

In the present series, NIM was mainly used as a warning of initial stressing of the nerve inducing the surgeon to change the dissection and waiting for the silencing of the spontaneous bursting of the involved branch. We believe that such a policy can play an important role in reducing immediate postoperative facial nerve weakness as described by different authors 2 30.

Microsurgery is a discipline of multiple ENT subspecialties requiring optical magnification and 3D view. The microscope is an important tool for the success of many of the most complex and difficult surgical procedures in medicine today 33. The interchangeable lenses (200-400 mm) allow a working distance that is appropriate to the depth of the various surgical approaches in otolaryngology 34. MAP improves the surgeon’s view, with better magnification and resolution, and better and more stable light source, allowing for fine discrimination of the terminal branches of the facial nerve from the vessels and the salivary ducts, even when neoplasms deeply adhere to the nerve (Fig. 4). Con-

![Fig. 4. Microscopic assisted dissection of the perinevrium in a malignancy.](image-url)
Microscope-assisted parotidectomy with intraoperative nerve monitoring

Subsequently a more fine dissection can be performed with precise haemostasis around the vasa nervorum, with reduction of postoperative facial nerve dysfunction rate. Average operation time for benign lesion was 221 minutes (range of 120-350). In our series, the mean operative time also includes procedures in which the identification of the facial nerve was performed by surgeons in training, which explains the longest operative times observed.

Facial nerve preservation rate changes according to different studies (Table IV). Cristofaro et al. reported a transient and definitive facial paralysis rates significantly more frequent after superficial parotidectomy than after extra-capsular dissection (20% versus 4.5%, and 2.2% versus 0%, respectively), involving mainly the mandibular branch in both techniques. In our series, the MAP used together with the NIM was associated with very limited postoperative facial weakness rates: after procedures performed for benign lesions, and all the definitive weaknesses were limited to one peripheral branch and of grade II according to the House-Brackman classification. Patients treated for benign tumours of the extra facial portion of the gland without inflammatory behaviour (n = 91) experienced 4.4% facial nerve temporary weakness rate and no permanent palsy. In the literature, inflammatory lesions adherent to the nerve are associated with postoperative facial weakness. Abscesses are uncommon complications and rarely require surgical revision; we never observed this complication in our series. Bleeding and haematomas occur after 3-7% of procedures. In the present series, immediate bleeding requiring revision was observed after 4.5% of the parotidectomies, and it was generally due to the accidental cauterisation of the branch of the stylomastoid artery that we think should be constantly ligated. Frey's syndrome after parotidectomy has been reported in 18%-50% of cases. In our series, it was observed in 24.1% of patients treated for benign pathology. Surgical and non-surgical treatments of Frey’s syndrome have been proposed, but the outcomes are disappointing since only temporary relief is achieved.

The GAN is frequently sacrificed during parotid surgery especially if runs close to the tumour, with consequent numbness around the ear lobe but a modest impact on patient quality of life. Moretti et al. suggest that saving as many branches of the GAN as possible during parotid surgery could be useful in reducing hypo-dysaesthesia. In the present study we noticed that numbness decreases progressively over time and is not reported as a main postoperative problem by patients.

Source No. of cases Temporary Permanent
First bite syndrome is facial pain localised in the parotid area and associated with severe cramps or spasms; although it has been estimated to occur after 9.6% of all procedures 48, we did not observe this condition in our series. Surgical incision and the removal of parotid tissue impact aesthetically on a visible area of the head and neck, but in literature only a small percentage of patients complain of scar and/or depression of the surgical area 34. In our series, scar was commonly related to the Blair’s incision more frequently used in elderly or males, but in females, if requested and possible in relation to the site and size of the tumour, a modified intra-canal facelift incision was performed with optimal results. Nowaddays, the facelift approach is considered a cosmetically superior approach to parotid tumours as confirmed by objective data 49. A long follow-up is recommended even in patients treated for benign neoplasms, since the mean interval between recurrences reported in literature is 7.0 ± 5.3 years for first recurrence 50. A limit of the present series is a follow-up no longer than 6 years. The most important cause of recurrence is rupture and incomplete removal of the tumour 51. Recurrences reported in literature is 7.0 ± 5.3 years for first recurrence 51. Although our survival data should be considered with caution since only 21 patients of 46 had a follow-up longer than 2 years, 5-year DSS and OS rates of our patients with parotid malignancies (83% and 70.6%) were comparable to those reported in the literature (78% and 58%) 55. As observed by Xiao et al. 56, N+ patients of our series experienced worse survival rates compared to N0 patients (5 years DSS and OS of 76.4% and 54.3% vs. 87% and 80.4%, respectively).

Conclusions

The surgeon’s experience is the main guarantee for facial nerve preservation and low recurrence rates during parotidectomy. In our experience, superficial parotidectomy for benign tumours not directly involving the nerve is a safe procedure with minimal risk for facial nerve injury. Inflammatory lesions requiring surgical treatment can be burdened by a moderately higher risk of temporary or permanent facial nerve dysfunction; as a consequence, precise counselling with the patient is mandatory, as well for patients undergoing surgery for malignancy. Minor complications such as numbness of GAN areas and Frey’s syndrome do not usually represent major discomfort for patients compared to facial nerve damage.

SUMMARY
Free flap surgery is overall considered the gold standard in head and neck reconstruction, with a success rate of about 95%. The management of a total flap necrosis and which solution, between a pedicled or a second free flap, is safer for a salvage procedure is still controversial. Object of this study is to describe the authors’ management of total free flap loss in head and neck reconstruction and compare the choices and results to those reported in the literature. From January 2012 to January 2016, 149 consecutive free flaps were performed at the Maxillo-Facial Operative Unit of the Hospital Casa Sollievo della Sofferenza in San Giovanni Rotondo (Italy) for reconstruction of head and neck defects. Of these, 6 flaps were lost due to a total necrosis. In 5 cases it was decided to harvest a second free flap, and in the remaining patient a temporalis muscle flap was used. All the free salvage flaps were successful, without complications and with a good aesthetic and functional recovery. Analysing the data obtained, and comparing them with those reported in the literature, it can be concluded that a second subsequent free flap can be considered an ideal and safe procedure in salvage surgery.

KEY WORDS: Free flap failure • Salvage free flap • Head and neck reconstruction • Flap loss management

Materials and methods
From January 2012 to January 2016, 149 consecutive free flaps were performed by the same surgeon at the Operative Unit of Maxillo-Facial Surgery of the Hospital Casa Sollievo della Sofferenza in San Giovanni Rotondo.
Our cohort consisted of 139 patients, 102 males and 38 females, with a mean age of 65.4 (36-88). Almost all the reconstructions were secondary to oncological resections. The pathological and reconstructive details are shown in Table I. The most common reconstructive options were the antero-lateral thigh (n = 50) and the radial forearm (n = 49) free flaps. Four patients underwent two free flap reconstructions because of the reoccurrence of the disease. One case had a simultaneous double free-flap transfer (fibula + ALT). In all cases flap vitality was controlled through clinical monitoring.

Functional and aesthetic outcomes were evaluated after 6 months, following the scores listed in Table II, using a questionnaire filled out by patients and as judged by a commission of three colleagues.

### Results

In a group of 149 consecutive free flaps, there were 6 flap losses in 6 different patients with an overall success rate of 96%. Of these there were 4 males and 2 females, with a mean age of 52 years (range 25 and 69 years). Table III lists the type, aetiology, clinical details of the flaps lost and subsequent treatment. We observed total necrosis of three fibula flaps, used for the reconstruction of mandibular (n = 2) and maxillary (n = 1) defects, one ALT flap, performed after a total glossectomy and two latissimus dorsi/scapular flaps performed to reconstruct maxillary defects. We did not observe any early necrosis: the first signs of necrosis were detected between the 7th and 13th day after surgery (mean time: 10.6 days). In one case (Patient 4), there was a massive haemorrhage due to the rupture of the common carotid artery: the vascular procedure performed in urgency resulted in a thrombosis of the flap’s pedicle. This was the only patient who had undergone previous radiotherapy. In one case, we observed a late infection (Patient 6) that resulted in a total flap loss. The other four cases had unknown causes of necrosis.

In five of the six patients a second subsequent free flap was performed, with a success rate of 100%. In one case, we decided to reconstruct the palate defect using a temporalis muscle flap. The donor sites of the salvage free flaps were the antero-lateral thigh (n = 3: subsequent to 1 ALT flap, 1 fibula flap and 1 combined scapula + latissimus dorsi flap), the fibula (n = 1: secondary to a fibula flap loss) and the latissimus dorsi (n = 1: after a combined latissimus-scapula free flap necrosis). The microvascular anastomoses were made on the same side in four cases (Table IV). In one patient, there was the necessity to use the contralateral neck vessels. No vessel grafts were required.

The salvage procedure was made during the same hospitalisation in four patients, within 26 days after the first surgery (mean time: 20 days). Two patients were discharged and after a mean of 44 days they were readmitted and underwent the salvage procedure with a new free flap. The mean hospitalisation time after the second surgery was 15.3 days (range: 1-20 days).

### Table II. Diet, speech ability and aesthetic scores.

#### Diet
1. Poor swallow ability
2. Liquid diet
3. Soft diet
4. Free diet

#### Speech ability
1. Not intelligible speech
2. Difficult to understand
3. Acceptable speech
4. Normal speech

#### Aesthetic results
1. Poor
2. Acceptable
3. Good
4. Excellent
No local or systemic major complications were observed. Functional and aesthetic outcomes are shown in Table V. Speech ability was normal in three patients and acceptable in two cases. In only one patient was speech described as difficult to understand. Considering diet and swallowing ability, four patients expressed the capacity of eating a soft diet, one patient can only feed himself with a liquid diet and one patient achieved the possibility of a normal diet after implants. The commission of colleagues who assigned an aesthetic score observed excellent aesthetic results in two patients, good results in one patient and acceptable results in three cases.

**Discussion**

Free flap surgery is considered a reliable and safe procedure for head and neck reconstruction. The success rate of a free flap described in the literature is about 95% 1-3. In our cohort, we observed a rate of 96% in 149 consecutive procedures. Despite the high success rates, free flap losses still occur at a rate of about 1% to 6% 6. The risk factors for a total flap loss are still unclear. Preoperative or previous radiotherapy is reported to be associated with a higher risk of free flap failure and complications 7. Radiotherapy produces, in fact, macro and microscopic alterations on vascular structures 8-10. In our
According to Corbitt \(^{14}\), who reported similar findings, both the artery and vein were thrombosed and the detection of flap compromise occurred late (mean: 10.6 days; range: 7th-13th day after surgery). Thrombosis on postoperative day 5 or later after microvascular reconstruction (late thrombosis) is reported to account for 10\% to 28\% of all thromboses \(^{15}\). Even if free flaps are believed to undergo revascularisation via the surrounding tissue and are able to survive without pedicle flow for several days after surgery, compromised recipient beds (such as irradiated tissue), chronically infected wounds and ischaemic vascular disease can interfere with free flap revascularisation, making the flap dependent on the pedicle for a longer period of time \(^{15,16}\).

In 5 of our 6 cases, the aetiology of the flap loss could not be determined. According to Corbitt \(^{14}\), who reported similar findings, both the artery and vein were thrombosed and the detection of flap compromise occurred late (mean: 10.6 days; range: 7th-13th day after surgery). Thrombosis on postoperative day 5 or later after microvascular reconstruction (late thrombosis) is reported to account for 10\% to 28\% of all thromboses \(^{15}\). Even if free flaps are believed to undergo revascularisation via the surrounding tissue and are able to survive without pedicle flow for several days after surgery, compromised recipient beds (such as irradiated tissue), chronically infected wounds and ischaemic vascular disease can interfere with free flap revascularisation, making the flap dependent on the pedicle for a longer period of time \(^{15,16}\).

Several authors \(^{12,13}\) have reported that age alone should not be considered as a contraindication or an independent risk factor when considering free-tissue transfer. Ferrari \(^{12}\) observed a successful free-flap rate of 98.2\% in 54 flaps harvested in patients over 75 years of age and a successful rate of 96.2\% in 306 of the 318 flaps performed in those under 75 years. Tarsitano \(^{13}\) described a similar success rate in patients aged ≥ 75 years compared to the general population. Considering our limited series of total flap loss, we observed a mean age of 52 years (range from 25 to 69) with no patient over 75 years.

Hypercoagulable states, the development of severe infection, external compression and errors in flap harvesting and management of the pedicle can be further causes of flap loss.

In 5 of our 6 cases, the aetiology of the flap loss could not be determined. According to Corbitt \(^{14}\), who reported similar findings, both the artery and vein were thrombosed and the detection of flap compromise occurred late (mean: 10.6 days; range: 7th-13th day after surgery). Thrombosis on postoperative day 5 or later after microvascular reconstruction (late thrombosis) is reported to account for 10\% to 28\% of all thromboses \(^{15}\). Even if free flaps are believed to undergo revascularisation via the surrounding tissue and are able to survive without pedicle flow for several days after surgery, compromised recipient beds (such as irradiated tissue), chronically infected wounds and ischaemic vascular disease can interfere with free flap revascularisation, making the flap dependent on the pedicle for a longer period of time \(^{15,16}\).

Probably in our group of patients the reduced or absent revascularization via the surrounding tissues added to late impairment of the pedicle (kinking, compression, misdiagnosed infections, etc.), which was the cause of the delayed loss of the flap.

Few studies have been published about the best way to manage the loss of a free flap, and the use of a subsequent salvage free flap is still a controversial issue. The hesitation is due to concerns regarding lack of recipient vessels, as well as increased risk of a second flap loss and postoperative complications. Different authors, in fact, have described higher rates of failure of a second free flap reconstruction, with success rates varying from 28\% to 89\% \(^{9,10,12}\). Bozikov \(^{17}\) observed that free flap failure was 4.6 times more likely to occur after a salvage free flap transfer with a success rate of 53\%. Ross \(^{18}\) in a series of 30 patients described a success rate of 73\%, a percentage significantly lower in comparison with second free flaps performed for recurrences. On the contrary, our results, even if on a small group of patients, show a higher rate of success (100\%) that mirrors the experiences of Wei of 94.1\% \(^{19}\), Alam and Khariwala of 100\% \(^{20}\) and Corbitt of 96.4\% \(^{14}\). Such success rates suggest that free flaps can be still a safe option even after an initial failure.

Wei \(^{19}\) reported the necessity to reach the contralateral neck for recipient vessels in 35\% of cases, and the use of interpositional vein grafts in the 30\% of cases. In our experience, in only one patient there was the necessity to reach the contralateral vessels, and venous or arterial grafts were not used in any case. Accordingly to Corbitt \(^{14}\), in some cases we re-used vessels that had previously been used for the initial free flap, without complications. Moreover, the rich vascularity of the head and neck often allows finding adequate recipient vessels, even after prior resection, neck dissection and free flap reconstruction.

The choice of the donor site should be made based on prognosis, general conditions and functional needs. Ideally, a free flap lost should be replaced by the same option if the first selection of the donor site has been correctly done. When prognosis is poor, the patient has comorbidities and bony reconstruction is not mandatory to obtain adequate functional rehabilitation, a soft tissue free flap can be chosen instead of an osseous flap. It is, in fact, characterised by lower donor site morbidity and faster re-

habilitation time. Even if the overall complication rate in patients who undergo a subsequent free flap attempt is reported to be slightly higher than those who were primarily reconstructed, in our cases we did not observe any local or systemic complications. The relatively short times of hospitalisation after the second free flap (mean: 15.4 days; range: 11-20 days) show the possibility to obtain quick rehabilitation of patients even after a salvage procedure. Moreover, satisfactory results, both in terms of function and aesthetics, were observed. We acknowledge that the relatively small number of cases in this series, particularly of patients who underwent secondary pedicled flap reconstruction, does not permit meaningful comparison between free and regional flaps. However, more extensive studies have shown that free flap reconstruction usually results in superior functional outcomes. Moreover, higher rates of local complications (fistulas, wound dehiscences, pedicle retraction, etc.) are reported in literature for pedicled flaps with respect to free flaps, both after primary and salvage harvesting. These data confirm our opinion that a second subsequent free flap should be considered as the first option after the total loss of a free flap in most cases. It represents, in fact, the technique that allows the best functional and aesthetic results, together with low complication rates and acceptable hospitalisation times. However, we agree with Corbitt in that good surgical and medical judgment, together with a careful primary selection of the patient and serious analysis of causes of loss, are crucial for the success of salvage free flaps.

Conclusions
The reconstruction of a head and neck defect after a free flap failure can be challenging for the surgeon. Even if pedicled flaps are classically considered the mandatory choice in salvage surgery after a free flap loss, accordingly with the most recent reports we consider the use of a subsequent second free flap the first option in salvage surgery. Despite major technical complexity and longer operative times, free flaps are reliable and safe procedures that bring the best aesthetic and functional results. The high success rates of the subsequent salvage free flaps and, on the contrary, the poor results and higher local complication rates of pedicled flaps, suggest that most patients would benefit from a reattempt at microvascular reconstruction.

Clinical analysis of Hashimoto thyroiditis coexistent with papillary thyroid cancer in 1392 patients

Analisi clinica dell’associazione fra tiroidite di Hashimoto e carcinoma papillare della tiroide in 1392 pazienti

SUMMARY

Papillary thyroid carcinoma (PTC) is the most common malignant tumour of the thyroid. The effect of the concurrent presence of Hashimoto’s thyroiditis (HT) and PTC is still under debate. The aim of this study is to investigate the influence of coexistent HT on prognostic outcomes and the association of coexistent HT with clinicopathological features. The demographic and clinicopathological data of 1,392 patients who underwent surgery in our hospital from 2007 to 2016 was collected and analysed. Among 1,392 PTC patients, the rate of HT was 25.6%. There were significant differences in the mean levels of thyroid stimulating hormone (3.27 vs. 2.41 μIU/L, p < 0.01), thyroperoxidase antibodies (110.31 vs. 131.2 U/ml, p < 0.01) and thyroglobulin antibodies (131.90 vs. 113.53 ng/ml, p < 0.01) between the two groups. PTC patients with HT had the following characteristics compared to patients without HT: smaller tumour size (p < 0.01), female predominance (p < 0.01) and higher rate of multifocality (p = 0.024). In addition, patients with HT had a significantly lower rate of lymph node metastasis (LNM) and advanced TNM stage than patients without HT (all p < 0.01). Multivariate analysis found that both age and multifocality were significantly associated with central LNM in HT patients (p < 0.01, p = 0.019, respectively). Extrathyroidal invasion and TSH level were also significant independent factors for lateral LNM in HT patients (p < 0.008, p = 0.04, respectively). HT is associated with a significantly higher risk of PTC. The coexistence of HT in PTC patients is associated with favourable clinical outcomes compared to PTC without HT. Total thyroidectomy and prophylactic central compartment lymphadenectomy should be a choice for PTC patients with HT.

KEY WORDS: Hashimoto’s thyroiditis • Papillary thyroid cancer • Clinicopathologic characteristics

RIASSUNTO

Il carcinoma papillare (PTC) è il più comune tumore maligno della ghiandola tiroide. L’effetto della concomitante presenza della tiroidite di Hashimoto (HT) e del PTC è ancora oggetto di studio. Scopo di questo studio è analizzare la coesistenza di una concomitante HT circa l’outcome prognostico e eventuali associazioni clinico-patologiche. Abbiamo raccolto ed analizzato i dati demografici e clinicopatologici di 1392 pazienti che sono stati sottoposti a chirurgia nel nostro ospedale dal 2007 al 2016. Fra i 1392 pazienti con PTC, la percentuale di coesistente HT era del 25,6%. Vi erano differenze significative tra i due gruppi nei livelli medi di ormone tireostimolante (3,27 vs. 2,41μIU/L, p < 0,01), anticorpi anti tireoperossidasi (110,31 vs. 131,2U/ml, p < 0,01) e anticorpi anti tireoglobulina (131,90 vs. 113,53 ng/ml, p < 0,01). I pazienti con PTC e HT avevano le seguenti caratteristiche seateate with quei de dei pazienti senza HT: tumori di dimensioni più piccole (p < 0,01), predominanza del sesso femminile (p < 0,01) ed un più alto tasso di multifocalità (p = 0,024). Inoltre, i pazienti con HT avevano un tasso significativamente basso di metastasi linfonodali (LNM) ed uno stadio di TNM più elevato rispetto ai pazienti senza HT (tutti p < 0,01). L’analisi multivariata ha evidenziato come età e multifocalità erano significativamente associate con metastasi nel compartimento centrale nei pazienti con HT (p < 0,01, p = 0,019, rispettivamente). L’invasione extratiroidea ed i livelli di TSH erano fattori significativamente indipendenti per le metastasi linfonodali laterocervicali nei pazienti con HT (p < 0,008, p = 0,04, rispettivamente). HT era associata ad un maggior rischio di sviluppare PTC. La coesistenza di HT in pazienti con PTC favoriva un miglior outcome clinico rispetto a quelli associati con PTC senza HT. La tiroidectomia totale associata allo svuotamento del compartimento centrale deve essere la prima scelta chirurgica nei pazienti con PTC e HT.

PAROLE CHIAVE: Tiroidite di Hashimoto • Carcinoma papillare della tiroide • Caratteristiche clinicopatologiche
Introduction

Thyroid cancer is the most common malignancy of the endocrine system, and its incidence rate is rapidly increasing by an average of 4.5% per year from 2007 to 2011. Approximately 70% to 80% of thyroid cancers are papillary thyroid carcinomas (PTCs), which exhibited a relatively benign clinical course. Hashimoto’s thyroiditis (HT), also called chronic lymphocytic or autoimmune thyroiditis, is the most common inflammatory thyroid disease. The incidence worldwide is estimated to be 20%-25% of all thyroid disease. Since its first description by Dailey et al. in 1955, many aetiologic and epidemiological studies have investigated the relationship between PTC and HT. Some authors have demonstrated that PTC with HT is associated with pathologic factors that indicate decreased tumour aggressiveness, such as small tumour size and low stage. It has also been associated with lower rates of recurrence, better locoregional control and longer overall survival. Other authors have shown no relationship between the presence of HT and tumour aggressiveness. Nowadays, the correlation between the two diseases with regards to pathogenesis and prognostic outcomes is still unclear.

Given the relatively high incidence of both diseases and the ongoing debate, we undertook a retrospective study to investigate the potential relationship between PTC and HT, and the effect of coexistent HT on the presentation, management and clinical outcomes of PTC patients.

Patients and methods

Between January 2007 and April 2016, there were 7,354 patients who underwent thyroid surgery in Liaoning Cancer Hospital & Institute. In the pathological review of these patients, 5,844 had benign lesions and 1,510 had malignant tumours. There were 1,392 PTCs, 58 follicular thyroid cancers, 23 medullary thyroid cancers, 15 lymphomas, 10 squamous cell carcinomas and 12 undifferentiated carcinomas. Among all patients, 1,682 were diagnosed as having pathological changes consistent with HT, while 5,672 were identified without HT. Pathologically-demonstrated HT was defined as the presence of diffuse lymphoplasmacytic infiltration, germinal centres and enlarged epithelial cells with large nuclei and eosinophilic cytoplasm. Only peri-tumoural lymphocytic infiltration was not regarded as HT.

Thyroid lobectomy with isthmusectomy was performed in 520 patients, whereas total thyroidectomy was performed in 872 cases. During lymph node resection, the central compartment was delimited superiorly by the hyoid bone, inferiorly by the substernal notch, laterally by the median portion of the carotid sheath and dorsally by the prevertebral fascia. Central neck dissection without lateral compartment neck dissection was performed in 785 patients. Comprehensive neck dissections such as radical neck dissection and modified neck dissection were performed in 495 patients, and 143 of these underwent bilateral neck dissection.

The following variables were considered: age, gender, thyroid function tests, fine needle aspiration biopsy (FNAB), tumour size, multifocality, extrathyroidal invasion, extension of surgery, lymph node metastasis (LNM), TNM stage, recurrence and distant metastasis. Patients were staged according to the seventh edition of the UICC/AJCC TNM staging system. This study was approved by ethical committees of our hospital, and informed consent was obtained from each patient. In addition, the AMES clinical staging system and the MACIS scoring system were used to evaluate the prognostic outcome. The AMES staging system divides patients into two groups: low risk (i) females < 51 years and males < 41 years without distant metastasis, and (ii) elderly patients with tumours < 5 cm with no extrathyroidal extension of the papillary carcinoma and high risk (i) patients with distant metastasis and (ii) females ≥ 51 years and males ≥ 41 years with tumours ≥ 5 cm or extrathyroidal extension if it is papillary carcinoma. The MACIS staging system has established that high score is strongly correlated with poor prognosis. It is obtained by adding 3.1 if the patient is ≤ 39 years or 0.08 × age if the patient is > 40 years, +0.3 × tumour size in cm, +1 if the tumour is not completely resectable, +1 if it is locally invasive and +3 in the presence of distant metastasis. Patients are divided into four groups: group 1, < 6; group 2, 6-6.99; group 3, 7-7.99; and group 4, ≥ 8.

Preoperative diagnostic evaluation

Diagnosis and preoperative evaluation of each patient were performed according to a strategy that was not changed during the study period. All patients underwent careful history and thorough physical examination in our department. All patients who qualified for surgical treatment were subjected to thyroid ultrasonography, determinations of free thyroid hormones (T3, T4) and thyroid stimulating hormone (TSH), as well as thyroperoxidase antibodies (TPOAb) and thyroglobulin antibodies (TgAb). FNAB and ultrasonography-guided FNAB were also used. A suspicious malignant nodule was diagnosed in the presence of at least one of the following ultrasound images: micro-calcification, infiltrative margin, increased nodular vascularity, taller that wide on transverse view and hypo-echoic. Metastases to the lung and lymph nodes were evaluated by preoperative imaging studies, such as CT.
Follow-up
Patient progress was followed by physical examination, ultrasonography and CT to identify recurrence. Furthermore, we also used FNAB on suspected masses or lymph nodes, and cytopathologic diagnosis was obtained. All patients were closely followed after surgery until August 2016. The median follow-up duration of patients was 38.4 months (range, 3.1-125.3).

Statistical analyses
All statistical analyses were performed using the SPSS 16.0 statistical package (SPSS, Inc., Chicago, IL, USA). Cancer-specific survival was analysed using Kaplan-Meier survival curves, and comparisons were made using the log-rank test. In univariate analysis, two-tailed χ² were used for statistical comparisons. In multivariate analysis, logistic regression analysis applied to identify the significant clinicopathologic factors correlated with LNM. For all analyses, only p values < 0.05 were considered significant.

Results
In total, 25.6% of patients with PTC (357/1,392) had coexisting HT. The proportion of female patients in the HT group was higher than that in the non-HT group (91.6% vs. 65.2%, p < 0.01). More PTC was found in the HT group than those without HT (21.2% vs. 18.2%, p = 0.007) (Table I). The proportion of female patients in the HT group was higher than that in the non-HT group (91.6% vs. 65.2%, p < 0.01). More PTC was found in patients with HT compared with non-HT patients (21.2% vs. 18.2%, p = 0.007) (Table I). Of the 1,392 PTC patients, there were 278 males (20.0%) and 1,114 females (80.8%; ratio 1:4) with a mean age 45.04 ± 12.47 years (median 45 years; range 10-82 years). The mean tumour size was 1.85 ± 1.11 cm. The sensitivity of FNAB was 49.5%. In our study, 373 patients had multifocality, and extrathyroidal invasion was identified in 34.8% of the patients. Central lymph node involvement was identified in 295 patients, lateral lymph node involvement in 198 patients and central and lateral LNM in 182 patients. During lymphadenectomy, one to 34 lymph nodes were removed. The number of involved lymph nodes varied between 0 and 22. There were 896 patients with stage I disease (64.3%), 58 with stage II (4.2%), 242 with stage III (17.4%) and 196 with stage IV (14.1%).

Patients with PTC and HT appeared to be slightly younger than those without HT (mean age 44.14 ± 11.95 vs. 45.34 ± 12.63); this difference was not statistically significant (p = 0.197). A greater female preponderance was noted in the patients with HT compared with those without HT (p < 0.01). Compared with non-HT group, the patients with HT group had higher levels of preoperative TSH, TgAb and TPOAb (all p < 0.01). Mean tumour size in patients with HT was smaller than in those without HT (p < 0.01). Additionally, the rate of multifocality was significantly different between the two groups (31.4% vs. 25.2%, p = 0.024). There was no difference in extrathyroidal extension between the two groups (p = 0.085). In HT patients, central LNM had a lower frequency compared with non-HT patients (19.6% vs. 21.7%, p < 0.01). Patients with HT had a significantly lower frequency of advance-stage disease (p < 0.01). However, no significant differences were found in terms of recurrence (p = 0.787) and distant metastasis (p = 0.06) between the two groups. The clinicopathological characteristics of 1,392 patients are summarised in Table II.

A multivariate logistic regression analysis that included age, gender, tumour size, multifocality, extrathyroidal invasion and TSH level was performed to assess whether these clinicopathological factors were associated with LNM in PTC patients with HT. We found that age and multifocality were significantly associated with central LNM in HT patients (p < 0.01, p = 0.019) (Table III). Next, we investigated the risk factors associated with lateral LNM in PTC patients with HT. Extrathyroidal invasion and TSH level were significant independent factors for lateral LNM in HT patients, with odds ratio of 0.353 (95% CI, 0.164-0.757, p = 0.008), 2.223 (95% CI, 1.038-4.757, p = 0.04) (Table IV). Two well-established prognosis classification systems of PTC patients were used. Using the AMES staging system, the rate of high risk group of PTC patients without HT was slightly higher than that of patients with HT (18.6% vs. 14.8%). However, no significant difference was found between the two groups (p = 0.113). According to the MACIS scoring system, the trend was more evident between the two groups (13.8% vs. 8.7%, p = 0.012). The PTC patients without HT had a higher mean score than those with HT (4.80 vs. 4.52, p < 0.01) (Table V).

During the follow-up period, 13 cases (3.6%) experienced recurrence in the HT group: 6 had thyroid recurrence and 7 had lymph node recurrence. In patients without HT, a total of 41 patients (4.0%) developed recurrence: 16 had thyroid recurrence and 25 had lymph node recurrence. All these patients underwent re-operation, and they all remain alive with no symptoms of further recurrence after second surgery. There were 2 patients who had lung metastasis in the HT group. In patients without HT, 20 had lung metastasis, while one had bone metastasis. Overall, one patient in the HT group and 10 patients in the non-HT group died, but only 3 of these deaths were due to PTC or related

**Discussion**

The thyroid gland is affected by autoimmune attacks more than any other organ, with HT being the most common thyroid autoimmune disease. HT is regarded as a destructive tissue-specific autoimmune disease with detectable TPOAb and TgAb. It is characterised by widespread lymphocyte infiltration, fibrosis and parenchymal atrophy of thyroid tis-
The disease usually leads to hypothyroidism, which is characterised by a deficit of T3 and T4 and elevated TSH levels. A visible increase in the incidence of co-existent PTC and HT has been found during the past 20 years, and the association between the two diseases has been a topic of discussion. According to abundant data from the literature and a meta-analysis performed by Singh et al., PTC coexisted with HT 2.8 more frequently and its prevalence in various studies ranged from 0.5% to 38.0%\textsuperscript{7,19-21}. PTC was also found to occur almost twice as often as other types of thyroid cancer\textsuperscript{22}. The observed variability in the rates could be explained by ethnic, geographic, patient characteristics and environmental factors. Moreover, the variability might also be attributed to differences in the pathologic definitions and histopathologic interpretation of HT used\textsuperscript{20,23}. In this study, we found a similar rate (25.6%) as reported by others.

Long-term HT frequently leads to hypothyroidism, which elevates TSH levels. Thus, when considering whether HT is a risk factor for PTC, it is necessary to investigate the levels of TSH. TSH is known to have a trophic effect on follicular-cell thyroid cancer and those of follicular-cell

Fig. 1. Comparison of disease-free survival between groups.

Fig. 2. Comparison of overall survival between groups.
origin. Elevated TSH might potentially increase the risk of thyroid tumour because of TSH-induced proliferation of thyroid cells. Some authors have proposed that the development of thyroid autonomy, reducing TSH levels, may slow cancer progression. In our study, we found that the rate of PTC in patients with HT (21.2%) was much higher than in those without HT (18.2%), and TSH levels in HT patients were significantly higher compared to those without HT. These results indicate that HT might be a potential risk factor for PTC patients. We hypothesised that long-term HT causes elevated TSH, which probably is the main factor responsible for PTC. This hypothesis might also explain why some prospective studies had negative results in terms of the relationship between PTC and HT. Thus, in clinical practice, patients with thyroid nodules and who are suspected of having HT need to be carefully monitored since the possibility of malignancy is increased.

There are conflicting results with regards to the biologic behaviour of PTC in the presence of HT. Some studies have reported that the presence of HT in PTC patients has been related to lower T stage, less extrathyroidal invasion and less nodal metastasis compared to patients without HT in previous studies. Other studies have shown HT does not influence any prognostic factors such as size, extrathyroidal extension, or multifocality, thus showing no relationship between HT and PTC aggressiveness. Our results revealed that PTC patients with HT were significantly more frequent in the population of females in a lower age range, presenting with small lesion and multifocal disease, but also with statistically less extrathyroidal extension. Moreover, PTC patients with HT had early-stage disease and less LNM at the time of surgery. Although no significant differences were found in terms of recurrence and distant metastasis, the rates of both were lower in HT patients.

In recent years, many researchers have tried to elucidate the relationship between PTC and HT from pathophysiological standpoint. The proto-oncogene RET, which is located on chromosome 10q11.2 and encodes a transmembrane receptor-tyrosine kinase, might play an important role between PTC and HT development by RET/PTC rearrangement. This rearrangement has been described in the large majority of tissue with HT and without detectable PTC, which might exhibit progression to cancer from chronic thyroiditis. Some authors proposed that the mitogen-activated protein kinase signalling pathway, which is activated by the RET/PTC rearrangement, is crucial in the relationship between both diseases. Mutations in the BRAF gene are also common in thyroid tumours. Franco et al. reported that mice with thyroid-specific knockin of oncogenic BRAF present invasive thyroid cancer and have high TSH levels. However, when they were crossed with TSH-receptor knockout mice, the BRAF mutated gene was not able to induce cancer. Currently, few studies have investigated the effect of HT and the BRAF^{V600E} mutation on PTC patients. Additionally, Larson et al. found the PI3K/Akt signal pathway was highly activated in HT and thyroid cancer tissue, and they proposed that this is a molecular mechanism leading to carcinogenesis in HT. Further investigations are needed to explain the relationship between HT and these genes in PTC patients.

Although recent studies have investigated the impact of HT on PTC tumour behaviour, only several studies have reported its association with LNM. Jeong et al. found no difference in central LNM between PTC patients with and without HT, but they did not investigate additional factors associated with LNM. Kim et al. suggested that HT associated with PTC may protect against central LNM, and there was no significant association between the coexistence of HT and central and lateral LNM. We found that PTC patients with HT were associated with a low rate of central and lateral LNM (19.6% vs. 9.5%). It was suggested that the autoimmune response to thyroid specific antigens in patients HT might be involved in destruction of cancer cells expressing thyroid specific antigen in PTC, thus preventing recurrence and LNM. Additionally, we noticed that age and multifocality was significantly associated with central LNM in HT patients in multivariable analysis, and extrathyroidal invasion and TSH level were independent factors for lateral LNM. These results indicated a potential protective role of autoimmune thyroiditis in lymphatic tumour spread. However, the explanation for the difference in the rate of central and lateral LNM on the basis of whether HT is present is unknown.

Many studies have demonstrated that PTC patients with HT have better prognosis. Some authors revealed a positive correlation between HT in PTC patients and DFS and OS; hence, they concluded that these patients had a more favourable prognosis. Kashima et al. reported a mortality and 10-year DFS of 0.7% and 95% in HT patients, compared to 5% and 85% non-HT patients, respectively. In our cohort, PTC patients with HT tended to have a more indolent clinical course compared to those with PTC alone, including a lower rates of OS and DFS; however, the differences in overall survival did not reach statistical significance. Because prognosis of PTC is remarkably excellent, it is sometimes difficult to analyse survival differences between subgroups of PTC. At present, the AMES stage and MACIS scoring system are most commonly adopted for predicting survival and formulating selective treatment strategies for thyroid cancer patients. Thus, we also analysed prognostic outcomes separately for the low and high risk groups by AMES stage and MACIS scoring system. The results showed that the proportion of low risk patients with PTC and HT was higher, and these patients also had lower MACIS scores. Although some p-values did not reach statistical significance, our findings could possibly change with additional patients and a longer follow-up period.
HT by itself is not an indication for surgery, but concurrent malignancy or the presence of goiter should be treated by surgery as the preferred option. As for the extent of surgery in these patients, some authors are inclined to have total thyroidectomy to eliminate the possibility of a potential cancer. Total thyroidectomy not only allows for treating a disease already diagnosed based on FNAB, but also contributed to decreasing the rate of reoperation due to postoperative diagnosis of thyroid cancer. The various therapeutic strategies employed in HT patients have led to the present surgeons to present their own opinion. PTC is the most common thyroid cancer with the predilection for lymphatic spread, and central lymph nodes are usually in the target area in differentiated thyroid cancer with LNM. Thus, it is our belief that in view of the relatively high rate of PTC in HT, the strategy of surgical treatment of HT in these patients might include total thyroidectomy and prophylactic central compartment lymphadenectomy. Even if a second surgery is needed because of neck recurrence, a neck lymph node dissection will be sufficient without increasing the operational difficulty and risks of hoarseness and hypocalcaemia.

We acknowledge that there are several limitations in our study. First, it was retrospective and as such was limited by the content, accuracy and availability of the clinical records utilised. Further longitudinal prospective studies are required to assess the potential relationship between the two diseases, if any, and the pathogenetic mechanisms involved. Second, in some studies, HT and PTC may share a possible risk factor, namely excessive intake of iodine, and it has also been proposed that changes in iodine intake might be responsible for the increase of PTC with HT. However, we were not able to perform more detailed assessment for lifestyle, such as dietary iodine intake, and this potential confounding parameter for the relationship between PTC and HT were not investigated fully. In a recent study, the BRAFV600E mutation was present in 72.1% of HT patients with PTC and the rate was significantly lower compared to 81.1% found in patients without HT. Since it was not investigated in our study, it can be considered as another limitation. In addition, it is very difficult for us to assess the mean time of HT in patients with PTC. It is necessary that the studies on increased TSH causing PTC in HT patients should be investigated in the near future, which may provide more information for better comprehension of the relationship between PTC and HT.

In conclusion, we found a relatively common occurrence of HT in patients with PTC. Compared to patients with PTC alone, patients with HT were younger, predominantly female, had a smaller tumour size, multifocal and low stage disease at the time of surgery. Simultaneously, our results showed that HT may influence LNM in PTC patients. HT was associated with a reduced of central and lateral LNM, which indicated a potential protective effect. More studies on the immunoregulatory mechanism and molecular mechanisms, such as high iodine intake, mutations in proto-oncogenes, balance of cell proliferation and activation of kinase activity, are still needed to support or refute this association.

SUMMARY

The objective of the present study was to determine if there is correlation between signs of reflux laryngitis (RL) and reflux oesophagitis (RE) in patients with gastro-oesophageal reflux disease (GORD) symptoms. Laryngeal photography obtained from patients during oesophagogastroduodenoscopy were examined by two otolaryngologists experienced in the field of extra-oesophageal reflux regarding the presence and severity of RL. The presence of RE was evaluated by gastroenterologist. Smokers, heavy drinkers and patients with bronchial asthma were excluded from the statistical analysis. A total of 681 patients were analysed. RL was diagnosed in 367 (53.9%) cases, of whom 182 patients had mild, 118 moderate and 67 severe (Reflux Finding Score > 7) RL. RE was diagnosed in 103 (28.1%) patients with RL and in 80 (25.7%) patients without RL. Neither the difference between the overall group of patients with RL and those without (OR 1.141, 95% CI 0.811-1.605, p = 0.448), nor the differences between the respective subgroups of patients with mild, moderate and severe RL and those without RL were statistically significant. The OR and 95% CI for mild, moderate and severe RE and those without RE were statistically significant. OR and 95% CI for mild, moderate and severe RL were respectively 1.042, 95% CI 0.712-1.526, p = 0.834, 1.182, 95% CI 0.764-1.831, p = 0.453 and 1.0, 95% CI 0.566-1.766, p = 0.999 respectively. It can be concluded that there is no correlation between RL and RE in patients with GORD symptoms.

RIASSUNTO

Lo scopo dello studio è stato determinare l’esistenza di una correlazione tra i segni di laringite da reflusso (RL) ed esofagite da reflusso (RE) in pazienti con sintomi da malattia da reflusso gastroesofageo (GORD). Durante l’esecuzione di esofagogastroduodenoscopie, sono state ottenute fotografie laringee, le quali sono state esaminate da otorinolaringoiatri esperti di reflusso extra-esofageo al fine di valutare la presenza e la gravità di RL. La presenza di RE, invece, è stata valutata dai gastroenterologi. Fumatori, alcolisti e pazienti con asma bronchiale sono stati esclusi dall’analisi statistica. Sono stati analizzati 681 pazienti. RL è stata diagnosticata in 367 (53,9%) pazienti, dei quali 182 avevano una forma lieve, 118 una forma moderata, e 67 una forma severa (Reflux Finding Score > 7). RE è stata diagnosticata in 103 (28,1%) pazienti con RL e in 80 (25,7%) pazienti senza RL. In merito alla presenza di RE, la differenza tra l’intero gruppo di pazienti con RL e quelli senza RL non è stata statisticamente significativa (OR 1.141, 95% CI 0.811-1.605, p = 0.448), e allo stesso modo non si sono rilevate statisticamente significative le differenze tra ciascuno dei sottogruppi di pazienti con RL lieve, moderata e severa, e quelli senza RL. L’OR e il 95% CI per RL lieve, moderata e severa sono stati rispettivamente i seguenti: 1.042, 95% CI 0.712-1.526, p = 0.834, 1.182, 95% CI 0.764-1.831, p = 0.453 e 1.0, 95% CI 0.566-1.766, p = 0.999. In conclusione, non è risultata nessuna correlazione tra RL e RE in pazienti con sintomi da malattia da reflusso gastroesofageo.

Acta Otorhinolaryngol Ital 2017;37:401-405

Introduction

It is broadly accepted that reflux oesophagitis (RE) is present in less than one-third of patients with laryngopharyngeal reflux (LPR), and oesophagogastroduodenoscopy (EGD) is not routinely recommended for these patients by otolaryngologists1. On the other hand, some studies have shown that extra-oesophageal symptoms may be the first sign of severe RE, as well as of adenocarcinoma2. If a patient suffers from frequent typical symptoms of gastro-oesophageal reflux disease (GORD), such as heartburn and regurgitation, or experiences some of the “alarm symptoms” such
as dysphagia, odynophagia, weight loss, anaemia etc., EGD should be done to understand the severity of the pathological changes within the oesophagus. However, most patients with extra-oesophageal symptoms do not suffer from such symptoms. As a result of the above mentioned contradiction, otolaryngologists often struggle with a dilemma: should a patient with extra-oesophageal symptoms and signs of reflux disease be referred for EGD or not?

The objective of the present study was to determine if there is correlation between signs of reflux laryngitis (RL) and reflux oesophagitis (RE) in patients with GORD symptoms. If this were true, the presence of reflux laryngitis (RL), which is considered the most characteristic endoscopic sign of LPR, would mean that reflux changes within the oesophagus (erosive oesophagitis) could be expected frequently in patients with GORD symptoms and patient should be referred for EGD. From this point of view, laryngoscopy done by an otolaryngologist as a routine examination would bring additional information in decision-making process whether patient with GORD symptoms should be referred to upper gastrointestinal endoscopy. To our knowledge, this is the largest study to examine the association between RL and RE in patients with GORD symptoms, and the first study to use Reflux Finding Score (RFS) to quantify laryngeal changes for this reason.

Materials and methods

The prospective study was performed in accordance with the 1983 Declaration of Helsinki, the requirements of good clinical practice and all applicable regulatory requirements, and was approved by the Institutional Review Board. Written informed consent was obtained from all participants before initiating any procedure.

Patients undergoing EGD due to GORD symptoms (heartburn, regurgitation) and/or upper gastrointestinal discomfort/dyspepsia lasting for at least two months within the study period of January 2014 to December 2014 were included. Epidemiologic data (age, sex, BMI, bronchial asthma, smoking history, alcohol abuse) were obtained via questionnaire. The presence of RE was established and classified by a gastroenterologist according to the Los Angeles classification (grades A-D). The high-definition endoscope Olympus GIF H180 was used for all examinations. As part of the EGD, laryngeal photography of high-definition quality was obtained from all patients (Fig. 1). The presence of RL was determined from photographs by two otolaryngologists (KZ, PK) experienced in the field of LPR and blinded for the result of EGD. RFS proposed by Belafsky et al. was not used for the initial evaluation of laryngeal changes because it is not widely used as first-line by otolaryngologists. To make the results of our study widely usable, a much easier system of evaluation of the laryngeal changes was used. Three degrees (mild, moderate, severe) of RL were distinguished. Patients with changes limited to the posterior commissure or arytenoids (hypertrophy, oedema, erythema) were included in group I (mild changes). Patients with changes in both the posterior commissure and arytenoids (hypertrophy, oedema, erythema) were included in group II (moderate changes). Patients with more severe changes affecting at least three areas of the larynx (e.g. erythema of the arytenoids, oedema of the vocal cords, pseudosulcus vocalis, hypertrophy of the false vocal cords, ventricular obliteration, granuloma etc.) were included in group III (severe changes) (Fig. 1). After this initial selection, group III was re-evaluated using RFS. All patients in group III had RFS higher than seven, which is the diagnostic threshold for LPR for this tool.
Smokers, heavy drinkers and patients with bronchial asthma were excluded from the statistical analysis, because inflammatory changes of the larynx are very common within these groups of patients and the results of the study could be biased.

The presence of RE in the groups of patients with RL and without RL as well as in all three subgroups (mild, moderate, severe) of RL was statistically analysed. Univariate logistic regression analysis was used to assess the relationship between RL and RE – by odds ratios (OR) and their 95% confidence interval (CI 95%). The dependent variable was the presence of RE. Statistical analysis was performed using SPSS statistical package (version 19.0).

Results

A total of 1224 patients were recruited for the study, 35 of whom were excluded because of the low quality of their laryngeal photographs. An additional 508 patients (smokers, heavy drinkers, patients with bronchial asthma) were excluded, and thus 681 patients (303 male, 378 female, mean age 57, SD ± 16) were analysed.

RL was diagnosed in 367 (53.9%) patients, of whom 182 patients had mild, 118 moderate and 67 severe (RFS > 7) RL. RE was diagnosed in 103 (28.1%) out of 367 patients with RL and in 80 (25.7%) out of 314 patients without RL. We ascertained that RE was not statistically more frequent in the overall group of patients with RL (OR 1.141, 95% CI 0.811-1.605, p = 0.448), nor in the subgroups of patients with mild, moderate and severe (RFS > 7) RL than in patients without RL. The OR and 95% CI for mild, moderate and severe reflux laryngitis were 1.042, 95% CI 0.712-1.526, p = 0.834, 1.182, 95% CI 0.764-1.831, p = 0.453 and 1.0, 95% CI 0.566-1.766, p = 0.999 respectively.

Discussion

LPR and its relationship to GORD and RE continues to be a controversial issue because there is a lack of diagnostic criteria and inconsistency in response to therapy. Nevertheless, it is a very real problem and affects hundreds of thousands of patients annually. It is estimated that up to 10-15% of all visits to otolaryngology offices are prompted by manifestations of LPR. One of the daily dilemmas otolaryngologists struggle with concerns whether or not a patient with GORD symptoms who do not fall within the “alarm symptoms” group and with concurrent signs suggesting LPR should be referred for EGD to determine the extent of pathological changes in the oesophagus.

While our understanding of LPR continues to evolve, one fact is already clear. LPR is considered to be a distinct disorder from GORD, with a different pathophysiology. When compared to the oesophageal mucosa, the laryngeal mucosa is more susceptible to injury, which may be caused by much lower levels of acid and pepsin exposure than those capable of damaging the oesophageal epithelium. Moreover, the negative role of biliary laryngopharyngeal reflux in the pathogenesis of chronic laryngeal changes has been revealed recently. This condition, as an acid one, seems to represent an important dangerous, endogenous risk factor involved in the pathogenesis of inflammatory, precancerous and neoplastic laryngeal lesions. As a result, many patients diagnosed with LPR do not suffer from the classic symptoms of GORD (heartburn, regurgitation) and erosive esophagitis. Therefore, EGD is not routinely recommended for patients with isolated LPR by otolaryngologists. For example, an international survey conducted by Book et al. demonstrated that only 5 (4.4%) of 120 otolaryngologists reported ordering EGD as a first-line adjunctive test for patients with suspected LPR.

On the other hand, some case control studies have shown an association between RE and RL. Also, it has been estimated that up to 50% of patients with laryngeal and voice disorders have reflux, prompting some authors to recommend endoscopic evaluation of the upper gastrointestinal tract in all patients with LPR. The reasoning is that some symptoms of more severe conditions within the oesophagus may be masked by empiric therapy. A peculiar subgroup of patients requiring EGD are those with chronic cough. Reavis et al. demonstrated that these individuals are more likely to have metaplastic changes of the oesophagus than those with classic symptoms of GORD.

In our study, we set out to understand whether RL, which is the most common and easy to access independent sign of LPR, is of diagnostic importance for prediction of RE in patients with GORD symptoms. We decided not to evaluate potential symptoms of LPR (voice problems, throat cleaning, globus pharyngeus, cough, etc.) and not to fill out questionnaire reflux symptom index in our study. The main reason is that symptoms of LPR and Reflux symptom index are even less specific than laryngeal signs of LPR, very prone to transitory changes and patient dependent with very high risk of subjective bias.

On the other hand, RL is considered to be one of the most characteristic signs of LPR. An international survey of 120 otolaryngologists conducted by Book et al. showed that arytenoid oedema and erythema and posterior commissure hypertrophy were considered the most typical signs of LPR by most. Similarly, a survey of more than 700 otolaryngologists revealed that the two signs most likely to be used to diagnose laryngitis associated with reflux were erythema and oedema of the larynx.

Nevertheless, it is very important to keep in mind that the signs of LPR are not very specific and can be the result of injury by non-GORD mechanisms (tobacco, alcohol, allergies, infection, postnasal discharge, vocal trauma etc.). This often leads to over-diagnosis of this condition and makes the study of the relationship between LPR and GORD (with or without RE) complicated and challeng-
ing. For example, Hicks et al. revealed at least one finding considered to be associated with reflux in 86% of 105 healthy volunteers without any throat symptoms. Additionally, abnormal laryngeal signs are more likely to be suspected when flexible rather than rigid laryngoscopes are used, suggesting that flexible laryngoscopy is more sensitive but less specific in identifying laryngeal tissue irritation. Besides the non-specificity of the signs currently employed in diagnosing LPR, an additional problem is the inter- and intra-observer variability of laryngoscopic exams. To improve reliability of the laryngoscopic evaluation, RFS was proposed by Belafsky et al. 19. Initial studies found good inter- and intra-observer reproducibility of this tool. However, RFS is seldom used in clinical practice as it is not user-friendly, as well as being difficult to remember and time-consuming. The reliability of this score has been questioned as well.

In the present study, three degrees (mild, moderate, severe) of RL were identified (Fig. 1) and patients divided into three groups accordingly. The groups “mild” and “moderate” included patients with laryngeal changes limited to the posterior commissure and/or arytenoids, for these changes are often construed by otolaryngologists as characteristic signs of reflux. The group “severe” included patients with many laryngeal signs of LPR, and all of these patients had RFS higher than seven. We did not find that RE was statistically more frequent in the overall group of patients with RL in comparison to the group of patients without RL. Moreover, RE was not statistically more frequent in subgroups of patients with mild, moderate and severe (RFS higher than seven) RL than in the group without RL. Thus our result is consistent with the result of a study evaluating the prevalence of laryngeal signs in GORD versus non-GORD patients (based on EGD) conducted by Vavricka et al. 20. The authors found that there was no difference between the groups, suggesting the lack of diagnostic specificity of laryngeal signs for GORD. 21. Also, another smaller study conducted by Tauber et al. did not find statistically significant differences in the above mentioned laryngeal changes between GORD and non-GORD groups.

Moreover, Cammarota et al. referred that 52 of 83 patients with laryngitis (63%) had no erosion of the oesophageal mucosa. The authors concluded that inflammation of the laryngeal epithelium (when defense mechanisms are absent) is more frequent than erosive oesophagitis in patients with chronic reflux symptoms. They recommend future studies in this area to better delineate these associations.

Going beyond the results of formerly mentioned studies, we selected a group of patients with severe laryngeal changes, which corresponded to RFS over seven. Even in this group of patients, RE was not found to be statistically more frequent. To our knowledge, this result is novel and has not been published in the literature to date.

As a result of our study, it can be concluded that laryngeal signs (reflux laryngitis) in patients with GORD symptoms are not of diagnostic specificity for RE. This supports the claim that LPR and GORD are two distinct diseases and that otolaryngologists cannot predict the presence of RE from the laryngeal examination. The other possible interpretation of our result is that signs of LPR are so non-specific and widely present in the population that the relationship with RE cannot be reliably established. Of course, in some cases these two entities can coexist and this can be the reason for the broad range of association reported in the literature. RE confirmed by EGD was reported in 26% (Paterson 1997), 43% (Deveney 1993 and Tauber 2002) and 62% (Koufman 1991) of patients with LPR. 6, 8, 12, 13. Likewise, RE was confirmed in 28% of patients with RL in the present study.

Conclusions

There is no correlation between reflux laryngitis and reflux oesophagitis in patients with GORD symptoms.

SUMMARY

It has become increasingly clear in the past decade that surgical management of obstructive sleep apnoea hypopnoea syndrome (OSAHS) is most successfully managed with multilevel surgery. We evaluated the outcomes of multilevel interventions comparing three different palatal techniques added to TORS: uvulopalatopharyngoplasty (UPPP), a modified expansion sphincter pharyngoplasty (ESP), inspired by the Pang expansion sphincter pharyngoplasty technique and the latest barbed repositioning pharyngoplasty (BRP). Thirty patients were retrospectively evaluated. Ten patients underwent UPPP by Fairbanks, 10 BRP and 10 a modified ESP already described. All patients underwent TORS, tonsillectomy and septo-turbinoplasty. For all cases, the following data were retrieved and revaluated: preoperative and postoperative apnoea-hypopnoea index (AHI), preoperative and postoperative Epworth Sleepiness Scale (ESS), pain visual analogue scale (VAS; 0–10) for the first 5 days postoperatively, palatal operative time for each surgical technique, discharge date and complication types and rate. Both BRP and ESP resulted in better postoperative AHI values and higher surgical success rates in comparison with UPPP. On the other hand, BRP was not more effective than ESP. ESP surgery time was significantly higher than UPPP, while BRP was the quickest procedure. In summary, ESP and BRP seem to be more effective than UPPP in a multilevel surgical robotic setting. However, being quicker, easy to learn and with a low rate of complications, BRP is a safe, effective and promising option for treatment of OSAHS patients.

KEY WORDS: TORS • OSAHS • Palatal surgery

RIASSUNTO

Negli ultimi anni si è diffusa l’opinione che la chirurgia multilivello nel trattamento della sindrome delle apnee ostruttive garantisca risultati più soddisfacenti. L’obiettivo del nostro lavoro è quello di confrontare tre tecniche palatali associate alla TORS: l’uvulopalatofaringoplastica (UPPP), l’expansion sphincter pharyngoplasty (ESP) e la barbed repositioning pharyngoplasty (BRP). Trenta pazienti, trattati con TORS, tonsillectomia e settoturbinoplastica e chirurgia palatale sono stati retrospektivamente studiati. I seguenti valori pre e post-operatori sono stati presi in considerazione: AHI, ESS, VAS per la valutazione del dolore, tempi operatori palatali, data di dimissione e complicanze (tipi ed incidenza). Sia la BRP che l’ESP hanno garantito dei valori postoperatorio di AHI inferiori rispetto all’UPPP con un maggior tasso di successo chirurgico. Dall’altra parte non è stato possibile dimostrare una superiorità della BRP sull’ESP. I tempi operatori più lunghi sono stati stati registrati nel gruppo ESP mentre i più brevi sono stati riscontrati nel gruppo BRP. Riassumendo, ESP e BRP sono risultate più efficaci dell’UPPP in un setting robotico multilivello. Inoltre, essendo una tecnica rapida, di facile apprendimento e dal basso tasso di complicanze, la BRP si presenta come una valida opzione chirurgica nel trattamento dell’OSAS.

Acta Otorhinolaryngol Ital 2017;37:406-409

Introduction

Today, transoral robotic surgery (TORS) for obstructive sleep apnoea-hypopnea syndrome (OSAHS) is a widely recognised effective therapeutic option.

It has become increasingly clear in the past decade that surgical management of OSAHS is most successfully managed with multilevel surgery. In particular, drug-induced sleep endoscopy (DISE) has shown that the hypopharynx and base of tongue are im-
important anatomic components of obstruction in OSAHS and therefore must be treated. During the last decades, several variations in palatal surgery have been proposed. We evaluated the outcomes of multilevel interventions comparing three different palatal techniques added to TORS: uvulopalatopharyngoplasty (UPPP), a modified expansion sphincter pharyngoplasty (ESP), inspired by the Pang expansion sphincter pharyngoplasty technique and the latest barbed repositioning pharyngoplasty (BRP).

Materials and methods

Thirty patients were retrospectively evaluated. The patients were randomly selected from the dataset including OSAHS patients treated surgically from May 2008 to December 2015 at the ENT unit of the Hospital Morgagni-Pierantoni, Forlì, Italy. Incomplete or very recent cases, with a postoperative polysomnographic evaluation shorter than 6 months, were excluded. Patients met inclusion criteria if they were 18 years of age or older, had failed continuous positive airway pressure as a nonsurgical treatment alternative and had an apnoea-hypopnoea index (AHI) of 20 or above. Patients who had had prior airway surgery, such as UPPP or tonsillectomy, were not eligible. Preoperative workup also included DISE. Only patients who were found to have significant collapse contemporarily at the retropalatal, retrolingual and hypopharyngeal levels were included. Three groups, each with 10 patients, were compared. Ten patients underwent UPPP by Fairbanks, 10 BRP and 10 a modified ESP already described. All 30 patients were treated with a robotic tongue base reduction with supraglottoplasty (SGP) by Vicini with temporary tracheostomy, tonsillectomy and septo-turbinoplasty. For all cases, the following data were retrieved and revaluated:

1. age;
2. sex;
3. preoperative BMI;
4. preoperative and postoperative AHI (all sleep studies were carried out in an unattended fashion by means of a Polymesam 8-channel; reviewed and scored by the same expert in sleep medicine according to the American Academy of Sleep Medicine Guidelines 2007);
5. preoperative and postoperative Epworth Sleepiness Scale (ESS), using the Italian version of the Epworth test that was adapted and tested for the Italian-speaking population;
6. pain visual analogue scale (VAS; 0–10) for the first 5 days postoperatively;
7. palatal operative time for each surgical technique (excluding tonsillectomy), as measured by our operating theatre electronic system;
8. discharge date;
9. complication types and rate.

The 3 groups were reasonably matched for sex, age, BMI and preoperative AHI. The definition of surgical response and success were a reduction from the preoperative AHI of at least 50% (response) and less than 20 events per hour (success). All clinical records were reviewed to examine all the differential features between the 3 groups potentially related to the different palate procedures applied. The study met the approval of the Local Board of Ethics (Institutional Review Board of the Hospital Morgagni-Pierantoni, Forlì). Statistical evaluation of pre-postoperative changes between groups was performed by means of Mann-Whitney, Kruskal Wallis and Wilcoxon tests, with the latter used to evaluate pre-postoperative changes in each group.

Results

The 3 groups showed no significant difference in F/M ratio (1/9 in all groups), age, BMI and preoperative AHI (Table I). The AHI decreased significantly after surgery in all groups except UPPP. ESS values, however, decreased significantly postoperatively in all groups (Table II). No significant differences in post-operative pain, deltaAHI (preAHI-postAHI) and hospital stay were recorded (Table III).

Surgical success rate was 90% in the ESP and BRP groups, and 50% in the UPPP group. ESP and BRP postoperative AHI values were significantly lower than UPPP. On the other hand, ESP and BRP did not show any differences in this measure. Both ESP and BRP post-operative ESS values were significantly lower than the UPPP figure, while no differences were seen between the first two groups. ESP surgery time was significantly higher than UPPP while BRP was seen to be the quickest procedure (Table IV).

No complications were recorded in any group.

| Table I. Pre-operative intergroup analysis. |
|-----------------|-----------------|-----------------|-----------|
|                | N   | Mean | Std. deviation | P         |

Discussion

In our sleep disorder breathing surgical practice, it is routine to perform multilevel surgery at the same surgical session. In our philosophy, TORS is just a step devised to address tongue base and supraglottic collapse, and is routinely carried out together with nose and palate surgery if required, according to DISE findings.

In the last years, many palatal techniques have been proposed. The introduction of the Pang ESP technique and, more recently, BRP have changed our OSAHS multilevel surgical setting. These two techniques soon became our first option with the robot-assisted multilevel procedure. Recently, the effectiveness of ESP was demonstrated in a meta-analysis by Pang. Moreover, our group reported on the superiority of ESP in a multilevel setting when compared to UPPP. However, in a 2015 study by our group it was shown that the BRP technique is feasible, safe and effective in the management of OSAHS patients. The use of a barbed suture allows to perform a quick procedure and to respect mucosal and muscular structures.

The purpose of the present study was to show the superiority of ESP and BRP compared to traditional UPPP in a multilevel setting, highlighting the advantages of BRP. Taking into account the retrospective nature of our study and the limited size of the three groups, our preliminary results may be interpreted as follows. Both BRP and ESP resulted in better postoperative AHI values and higher surgical success rate in comparison with UPPP. On the other hand, BRP was not more effective than ESP. ESP surgery time was significantly higher than UPPP while BRP was seen to be the quickest procedure. Furthermore, in our series no complications were recorded, likely due to the small size of our sample. However, we assume that the probability of bleeding is significantly lower in BRP patients, as the soft palate and the pharyngopalatine muscle are respected when performing this technique.

No difference in postoperative pain was recorded between groups, probably because all patients underwent tonsillectomy contemporarily.

The higher effectiveness of BRP and ESP may be interpreted considering their more focused action on the lateral wall area. Moreover, the authors feel that circular scarring and tension produce a significantly delayed reduction of oropharyngeal section in UPPP cases. In ESP, the same scar retraction would probably tend to straighten the angle between the plane of tonsillar fossa and the intrapalatal muscular flap, producing a progressive enlarging vector for the lateral wall and palate.
BRP, instead, allows to displace the posterior pillar (palatopharyngeal muscle) in a more lateral and anterior position to enlarge the oropharyngeal inlet as well as the retropalatal space. In a previous study published by our group, it was shown how this technique is easy to learn even for non-experienced surgeons, less time consuming and with no significant complications.\(^\text{12}\)

Conclusions

ESP and BRP seem to be more effective than UPPP in a multilevel surgical robotic setting. Being quicker, easy to learn and with a low rate of complications, BRP appears to be a safe, effective and promising option for the treatment of OSAHS patients.

SUMMARY

The planning of experimental studies for evaluation of nasal airflow is particularly challenging given the difficulty in obtaining objective measurements in vivo. Although standard rhinomanometry and acoustic rhinometry are the most widely used diagnostic tools, they provide only a global measurement of nasal dynamics, without temporal or spatial details. Furthermore, the numerical simulation of nasal airflow as computational fluid dynamics technology is not validated. Unfortunately, there are no available diagnostic tools to objectively evaluate the geometry of the nasal cavities and to measure nasal resistance and the degree of nasal obstruction, which is of utmost importance for surgical planning. To overcome these limitations, we developed a mathematical model based on Bernoulli’s equation, which allows clinicians to obtain, with the use of a particular direct digital manometry, pressure measurements over time to identify which nasal subsite is obstructed. To the best of our knowledge, this is the first study to identify two limiting curves, one below and one above an average representative curve, describing the time dependence of the gauge pressure inside a single nostril. These upper and lower curves enclosed an area into which the airflow pattern of healthy individuals falls. In our opinion, this model may be useful to study each nasal subsite and to objectively evaluate the geometry and resistances of the nasal cavities, particularly in preoperative planning and follow-up.

KEY WORDS: Nose • Manometry • Fluid dynamics • Airflow • Rhinomanometry

RIASSUNTO

La realizzazione di studi sperimentali per la valutazione dei flussi aerei nasali è particolarmente indaginosa, data la difficoltà di ottenere in vivo un’accurata misurazione degli stessi. Inoltre, sebbene la rinomanometria standard e la rinometria acustica rappresentino i metodi più utilizzati nella pratica clinica, esse forniscono solo una misura globale ed approssimativa dei flussi aerei nasali, senza definirne i particolari temporali o spaziali. Allo stesso modo gli studi sulla fluidodinamica computazionale rappresentano solo una simulazione numerica, ben lontana da quelle che sono le variabili anatomiche e fisiologiche delle cavità nasali. Pertanto, ad oggi, non esistono ancora strumenti diagnostici in grado di misurare oggettivamente la geometria delle cavità nasali, le resistenze ed il grado di ostruzione nei diversi sotto-siti nasali, elemento quest’ultimo fondamentale per una corretta programmazione chirurgica. Allo scopo di superare i limiti della diagnostica standard abbiamo elaborato un modello matematico basato sull’equazione di Bernoulli applicata alle cavità nasali di soggetti sani per lo studio dei gradienti pressori di vari sotto-siti nasali, che sono stati misurati grazie ad un particolare manometro digitale. Il nostro studio, unico in letteratura, ha identificato due curve limite che racchiudono un’area rappresentativa entro cui cadono i livelli “normali” di flusso in corrispondenza del vestibolo nasale. Il modello descritto potrebbe essere utile per studiare tutti i sotto-siti nasali sede di ostruzione ai fini di una corretta programmazione chirurgica e di un valido follow-up postoperatorio.

Acta Otorhinolaryngol Ital 2017;37:410-415
Introduction

Nasal obstruction is the most common symptom observed in rhinological practice, afflicting millions of people and accounting annually for over $5.8 billion in healthcare costs in the USA alone.

Deviated nasal septum is one of the most common causes of nasal obstruction and septoplasty is the third most common surgery performed by otolaryngologists. However, septal deviation may not always be the only cause of nasal obstruction. Indeed, there are many asymptomatic individuals with nasal deviation and many others suffering from nasal obstruction without septal deviation. Thus, despite successful surgical correction, many patients are not satisfied with the outcomes after septoplasty or nasal surgery in general, which might lead to medico-legal issues. Moreover, some investigators have criticised the high number of unnecessary nasal surgical procedures performed each year.

This happens because very often there are other causes responsible for nasal obstruction, such as nasal valve collapse or lateral wall insufficiency, which may alter the physiological dynamics of the nasal airflow.

For instance, in humans the physiological functions of nasal breathing (conditioning, warming and humidifying of inhaled air, smelling, etc.) are closely related to the mechanical properties of fluids. In healthy adults, most of the airflow occurs in the middle meatus, the nasal respiratory rate at rest is about 16 breaths/min and the airflow volume in a single inspiration is about 500 ml. The airflow velocity (V) depends on the strength of breath and on the width of a given nasal subsite, so that during a steady inspiration in standard conditions V is about 2-3 m/sec at the nostril level and 12-18 m/sec at the nasal valve area level.

Since the nasal valve and vestibular airflow accounts for 52.6%-78.3% of total nasal airway resistance, these sections are considered the main nasal airflow limiting structures. Thus, this anatomical and physiological narrowing at the "entrance" of the functional segment of the nose causes a significant increase in the velocity of the airflow and represents the accelerator of the inspired air. Therefore, any obstruction at this level results in a significant reduction in nasal airflow.

To summarise, effective nasal breathing requires certain airflow volumes, a pressure drop, temperature variations and the right proportions between laminar flow and turbulent flow regions, in addition to the ability to provide sufficient air to the lungs.

Hence, from a purely anatomical point of view, changes in the architecture of nasal cavities for pathological disorders, trauma or surgery may alter the nasal resistances and functions and, consequently, the mechanical properties of nasal airflow, which are strongly affected by the geometry of the airflow passage.

Unfortunately, to date, there are no diagnostic tools to objectively evaluate the geometry and mechanical properties of the nasal cavities and to measure nasal resistance and degree of nasal obstruction. Indeed, despite recent advances in the research of nasal diagnostic strategies, the currently available diagnostic tools for the study of nasal airflow and resistance have some limitations and the individual subjective sensations of the patients do not always match objective measurements.

For instance, the most widely used methods to evaluate the nasal airflow, standard rhinomanometry (RNM) and acoustic rhinometry (AR), can evaluate changes in overall nasal airflow and resistance, and measure cross-sectional areas in nasal cavity. However, due to the structural and physiological complexity of human nose, these techniques are not able to show sufficient details of dynamic airflow through the nasal cavity to fully evaluate many intranasal diseases and anatomical variations, whereas 4-phase rhinomanometry (4PR) might provide supplementary information; nonetheless, all open technical and mathematical inconsistencies conjoint with this technique have been clarified.

Furthermore, the numerical simulation of nasal airflow as computational fluid dynamics (CFD) technology, whose data are not yet validated, requires such a burden of time and resources that it cannot be routinely used.

For all these reasons, the treatment of nasal obstruction in daily clinical practice of otolaryngologists represents a challenge for researchers in constantly searching for reliable objective tests to quantify nasal obstruction. To overcome these limitations and to objectively measure nasal resistances, the degree and, primarily, the subsite of nasal obstruction, we developed a mathematical model based on Bernoulli’s equation applied to clinical practice with the help of the digital DDM-MG1 manometer Endoflower (Gamerra patented, 2007).

Materials and methods

The study was performed in accordance with the principles of the 1983 Declaration of Helsinki and was approved by the local board of medical ethics. Written informed consent was obtained from all participants prior to the inclusion in the study. Forty Caucasian subjects, non-smokers suffering from cephalgia and without lung disease or nasal obstruction, underwent nasal endoscopy and computed tomography (CT) scan, previously planned disease or nasal obstruction, underwent nasal endoscopy and computed tomography (CT) scan, previously planned.

The sample was homogeneous for age, sex and body weight (20 M 20 F; mean age 42.64 ± 13.1; BMI 22.9 ± 2.1 kg/m²).

To carry out pressure measurements, we used a DDM-MG1 manometer (Gamerra patented, 2007). Technical characteristics of the digital manometer were as follows: "Auto Zero" adjustable with respect of the atmospheric...
pressure; range of measurement = 0 +/- 100 mbar; over-
range pressure: max 300 mbar, resolution: 0.1 mbar (be-
tween 0 and 70 mbar), 0.2 mbar (between 70 and 100
mbar); accuracy at 23°C: +/- 0.5% mbar (between 0 and
70 mbar); +/- 1% mbar (between 70 and 100 mbar); tem-
perature range: 0° to + 40°C; not condensing humidity: 10
to 90% relative humidity.

Under endoscopic guidance we placed the probe of the
manometer in the nasal vestibulum corresponding to the
CT imaging of the same subsite. Furthermore, to confirm
the exact correspondence between the nasal point and the
CT scan we chose a point easily detectable corresponding
to the dome, part of the vestibulum.

Subjects were asked to slowly and deeply breathe through
the nose for 4 seconds, while the nasal section was checked
by video-endoscopy for the entire duration of the exami-
nation. The manometer was connected to a computer with
software for visualisation and recording of pressure values.

Images were acquired with an 8-slice CT scanner (Light-
Speed, GE Medical Systems, Milwaukee). The volume
datasets were processed by a workstation equipped with
OsiriX MD software (release 7.0.3, Pixmeo sarl, Bernex,
Switzerland) and axial images were reconstructed in
 coronal and sagittal planes using the MPR (Multi Planar
Reconstruction) protocol integrated in the software. The
perimeter of air sections was outlined with “pencil” func-
tion to obtain the geometric area measurement in cm².

To estimate the airflow rate through a defined nasal sec-
tion, we developed software depending on the mathemati-
cal model, based on an integral equation, concerning the
minimum and maximum value of the area delimited by
the two curves in Figure 1, carrying out the volume of the
nasal inhaled air for each inhalation.

Assuming the validity of Bernoulli’s equation, we can
calculate the gauge pressure in the vestibulum by consid-
ering one central point N within this duct. In this expres-
sion, we denote the pressure in N as \( P_N \). By considering
a second point O at the entrance of the nasal valve and by
taking the pressure in O equal to the atmospheric pressure
\( P_a \), we can write:

\[
P_N + \frac{1}{2} \rho V_N^2 = P_a \quad (1)
\]

where \( r \) is the density of air and \( V_N \) is the flow velocity in
the central part of one section of the nostril, assumed to
have circular shape with area \( S_N \) for simplicity. By taking
a parabolic profile as the one shown in Figure 2, we can write:

\[
V(r,t) = V_N(t) \left[ 1 - \left( \frac{r}{R} \right)^2 \right] \quad (2)
\]

where \( r \) is radial distance from point N, \( t \) is the time meas-
ured from the beginning of inhalation, and \( R \) is the radius
of the circular section of area \( S_N \) (Fig. 2).

Notice that in Eq. (1) the velocity profile \( V(r,t) \) is taken to
depend on time through the time dependence of the velocity
\( V_N \). Let us now calculate the flow rate through \( S_N \), so
that we write:

\[
q(t) = \int_{S_N} V(r,t) dS \quad (3)
\]

where \( dS = 2\pi r \, dr \) is the area of an elementary ring of
radius \( r \) and thickness within \( S_N \). By performing the inte-
gral, we found:

\[
q(t) = \frac{S_N}{2} V_N(t) \quad (4)
\]
The nasal airflow rate

The equation is based on the fluid dynamic criterion that the nasal airflow is concentrated in the centre of a hypothetical circumference, because most of the energy pushing the air through the nasal cavity is dissipated for effect of the laminar boundary layer flow (LBLF) against the nasal wall for which it is ineffective (Fig. 2).

Results

No complications were found during nasal manometry. In Table I we report the values of nasal sections expressed in mm², pressure in mbar and time in sec. We gathered experimental data for a deep breath of a standard-group subject. Observed data were pressure versus (t) time.

The data showed that the effective velocity regarding the

</table>

Pat = patient; sect. = section of the nose, mm²; mbar. = millibar; t/s. = time/second.
calculation of airflow rate is one half the time dependent maximum velocity.
In figure 3 we show the average of the standard group measurements as full circles.
By integrating this curve as a function of time we found that the volume of inhaled air in one nostril \( (K_1) \) was 221 ml and the total volume \( (K_{\text{inf}}) \) was 442 ml.
We compared the volume of inhaled air by the standard-group subject with an average reference value (250 ml) for each nostril, as reported in the literature.7
The standard deviations (SD) for each set of data at a fixed time were then calculated:

\[
\left[ (t_1) = 0.20, s(t_1) = 0.34, s(t_2) = 0.43, s(t_3) = 0.36, s(t_4) = 0.14 \right].
\]

These statistical parameters suggested the presence of two limiting curves, one below and one above the average representative curve depicted in Figure 1, enclosing an area into which the respiratory pattern of healthy people falls. Therefore, two limiting values of the volume of inhaled air per nostril exist: \( K_{\text{up}} = 191 \text{ ml} \) and \( K_{\text{up}} = 267 \text{ ml} \).

**Discussion**

Nasal surgery aims at improving nasal breathing, yet decisions pertaining to the need for surgical treatment implies a significant degree of subjective judgement by the surgeon.13, So far, NMR and AR are the most widely used tools to evaluate the nasal airflow, but they provide only a global airflow measurement, without temporal or spatial details. Furthermore, these methods do not suffice to reliably guide the surgeon in the choice of the best therapeutic strategy.14 In addition, they do not provide information about local details of nasal airflow, often of utmost importance from a clinical standpoint. Although AR produces a more detailed evaluation of the geometry of the nasal cavities, it does not evaluate the flow field, but only the geometric boundaries. Indeed, previous studies showed the validity of AR in the evaluation of functional outcomes following endoscopic surgery in correlation with volumetric CT, but it did not provide any information on the physiology of nasal pressures.16
Unlike NMR or AR, CFD showing the airflow characteristics in 3D can make accurate predictions about the variables of fluids in a computer model.17 For instance, many authors made airflow calculations by reconstructing the nasal geometry from CT sequences of healthy subjects, whose nose was assumed to be normal in terms of flow and symmetry.18 However, they pointed out some challenging aspects related to the geometric complexity of nasal airways: the non-uniqueness of standard measurement of engineering type procedures applied to humans, the presence of physical phenomena implicated (viscosity, flow conditions, Reynolds number, wall roughness, heat transfer, humidity, fluid tissue interaction, turbulence) and, most important, the fact that CFD studies are only simulations and the predicted results derived from complex calculations of the Navier-Stokes equation, which may not represent real-life conditions.
In our study, we evaluated the nasal airflow by means of a mathematical model based on the validity of Bernoulli’s equation in the central part of the nostril. To take account of nasal airflow viscosity, we applied a quadratic velocity profile in the nostril, whose section was assumed to be circular for simplicity. Under these assumptions experimental data, reporting the gauge pressure \( \Delta p \) inside the nostril as a function of time, were gathered by DDM-MG, Endoflower that allowed to study the pressure inside the nose, pointing the probe in the specific nasal subsite we wanted to investigate.

The inner nasal structures were assimilated to a sequence of tubes under stationary conditions in which single particles close to the centre of the flow described laminar trajectories without energy loss. Although this model represents a valid approximation for airflow away from the ducts, a viscous effect could be considered in the proximity of the walls of the nasal cavity. Therefore, in our model we assumed the validity of Bernoulli’s equation in the central part of the duct, where the gradient of the velocity profile could be considered to be negligible. To achieve mathematical computed values of the volume of air during a single inhalation act, obtained pressure values were processed with data from the corresponding CT scan slide.
We found that the average inhaled air volume in a single nostril in a standard-group subject during a deep breath was 221 ml, with an overall volume of 442 ml. Conversely, the literature reports values of 250 ml and 500 ml, respectively.

Our study, for the first time, identified two limiting curves, one below and one above an average representative curve, describing the time dependence of the gauge pressure inside a single nostril. These upper and lower curves enclosed an area into which the airflow pattern of healthy people falls. Two limiting values of the volume of inhaled...
The nasal airflow rate

air per nostril, $K_{up}=191$ ml and $K_{down}=267$ ml, were found. It can be argued that in order to measure nasal airflow a CT scan is needed and this would limit the clinical usefulness of the model. However, CT is not strictly necessary as the probe is placed under endoscopic guidance, which allows the perfect positioning of the probe at the chosen subsite. It is also to be considered that CT is often performed in any case as a diagnostic and preoperative tool for surgical planning.

Conclusions

In conclusion, despite recent advances in nasal diagnostics, there are still open questions on the management of nasal obstruction and on the opportunity to perform nasal surgery. Furthermore, given the lack of reliable tools to objectively measure nasal resistances and to identify the right subsite of nasal obstruction, the goal of this study was to allow clinicians to obtain pressure measurements over time at various subsites of nasal airway to identify which ones are obstructed. In the present study, a mathematical model has been applied to healthy subjects to assess the normal range of resistances, with the aim to compare, in future studies, these data with those from subjects with nasal obstruction at different subsites.

Acknowledgments

We are also deeply indebted to Anna Marino, MD, for her cooperation.

Cochlear implant in prelingually deafened oralist adults: speech perception outcomes, subjective benefits and quality of life improvement

Introduction

Cochlear implantation is the treatment of choice for patients affected with severe to profound sensorineural hearing loss. Until the mid 1990s, these patients were considered poor CI candidates, because improvement in speech perception was limited. However, several recent studies have suggested that the latest implant technology results in open-set speech perception abilities, although variability among individuals was great and performance lagged behind that of post-lingually deafened adults. These conclusions are mainly based on results obtained in small and heterogeneous samples. It is useful to underscore that in Italy since the sixties oralism has been the main rehabilitative choice for patients suffering with preverbal deafness. As a consequence, in Italy the vast majority of adult patients with preverbal deafness followed an oralist rehabilitation programme, and submitted to cochlear implant at our institution.

SUMMARY

The aim of this study is to report our results in a group of prelingually deafened adults, who followed an oralist rehabilitation programme, and submitted to cochlear implant at our institution. We evaluated 30 prelingually deafened adult patients, 18 males and 12 females, median age 35 years, of a group of 36 prelingually deafened adult patients consecutively submitted to unilateral cochlear implantation at the ENT Unit of the University of Pisa. After implantation, patients achieved significant benefits in terms of speech perception skills, including the ability to have telephone conversations in some cases, quality of life and their own perception of disability. According to literature data, the results herein reported are quite variable but generally satisfactory. Procedures other than traditional speech perception measures should be used to evaluate the benefits of cochlear implant in such patients, to comprehensively evaluate the global benefits, not only in terms of speech perception, but also in terms of quality of life and daily life.

KEY WORDS: Prelingual deafness • Cochlear implant • Quality of life

RIASSUNTO

Lo scopo di questo studio è riportare i risultati ottenuti in un gruppo di pazienti adulti con ipoacusia prelinguale, che hanno seguito un programma di riabilitazione di tipo oralista, sottoposti ad impianto cocleare nella nostra clinica. Sono stati analizzati 30 pazienti adulti, 18 maschi e 12 femmine, con un'età media di 35 anni, selezionati da un gruppo di 36 adulti con sordità prelinguale sottoposti ad impianto cocleare unilaterale nella U.O. Otorinolaringoiatria, Foniatria ed Audiologia Universitaria di Pisa. Dopo la procedura di impianto cocleare i pazienti hanno raggiunto significativi benefici in termini di percezione del linguaggio, inclusa la capacità di avere una conversazione telefonica in qualche caso; benefici sono stati raggiunti anche riguardo la qualità della vita e la percezione della propria disabilità. In accordo con i dati riportati in letteratura i risultati da noi presentati sono variabili ma generalmente soddisfacenti. Per valutare i benefici dell’impianto cocleare nei pazienti riportati in questo studio devono essere considerate altre procedure oltre a quelle tradizionali di valutazione della percezione verbale, così da poter apprezzare complessivamente i benefici, non solo in termini di percezione verbale ma anche di miglioramento della qualità della vita quotidiana.

PAROLE CHIAVE: Sordità prelinguale • Impianto cocleare • Qualità della vita
deafness seeking a CI consistently using hearing aids, have been following an oralist rehabilitation mode and developed oral language, even if at variable degrees of performance.

The aim of this study was to report our results in a group of 30 prelingually deafened adults, who followed an oralist rehabilitation program, and submitted to CI in our institution. Gains in speech perception abilities and subjective benefits are reported, as well as benefits in the quality of life. A correlation with individual factors is provided in order to define the impact of the different variables on outcomes.

Materials and methods

The sample was composed of 30 prelingually deafened adult patients, 18 males and 12 females, median age 35 years (IQR interquartile range): 28-42, range: 16-54) of a group of 36 prelingually deafened adult patients (83%) consecutively submitted to unilateral cochlear implantation at the ENT Unit of the University of Pisa (Italy), during the period from July 1999-July 2011. All prelingually deafened adult patients implanted in our institution were oral language users and consistently used hearing aids before implantation. The 30 patients enrolled in the study are those who gave their consent to participate to the study. Among the 6 implanted patients not included in the study sample, one is a not user, one has not come for follow-up at our centre for many years and the others do not come frequently for follow-up visits, as they live far from the centre.

Pre-operatively, all patients were submitted to comprehensive audiological evaluation, including a speech perception test without lip-reading with hearing aids, neuroradiological evaluation by petrous bone high resolution computed tomography (CT) and brain and inner ear magnetic resonance (MR). Aetiology of hearing loss was also investigated by molecular analysis of the connexin 26 and 30 genes, and mitochondrial DNA A1555G mutation analysis in all cases, and PDS gene mutation analysis in patients with a large vestibular aqueduct. The most salient features of patients are summarised in Table I.

Post-operatively, during follow-up visits, all patients were assessed by pure tone audiometry in a free field with the CI in use and to a speech perception test without lip-reading with the CI in use.

Pure-tone audiometry was conducted with an Interacoustics Clinical Audiometer AC40. When measuring the hearing threshold, both without HA and with HA, we assigned a value of 125 dB to any frequency threshold over the maximum output limit of the audiometer (105 dB for 0.25 KHz and 125 dB for 0.5 and 1 KHz, 120 dB for 2 KHz). Any vibrotactile sensation was excluded.

Speech perception was assessed using a speech perception test in Italian language both before (with hearing aids) and after implantation (with CI) in free field, by the same speech therapist in all the patients to avoid bias, with live voice, and without lip-reading. We evaluated the disyllabic words recognition score using lists of 20 disyllabic Italian words at a level of 65 dB.

In order to obtain information about personal factors and subjective benefits from CI, at the moment of the study setup we administered a questionnaire “University of Pisa Questionnaire” (UPQ) to all enrolled patients. This questionnaire was specifically developed by our research team and is a 40 question survey, divided into 3 sections. In the first section, pre-operative information, such as type of hearing aid, ability to have telephone conversations, perception of music and rehabilitation are collected; in the second section, the same aspects after implantation are investigated; in the third section, information about social life, education level and working life are recorded.

Patients were also submitted to the APHAB questionnaire to assess improvement in the patients’ own perception of the disability and in quality of life derived from CI procedure.

Table I. Summary of salient patient features.

Note: *4 patients (3 fetopathy rubella, 1 toxoplasmosis); **1 patient (mumps at 2 years) IQR, interquartile range
The questionnaire was administered both before and after implantation at the moment the study was initiated. Quality of life (QoL) was measured in all the patients after implantation and at the moment of study initiation by using the Italian version of the Short Form-36 Health Survey, version 1 (SF36 v1). Authorisation from the company was obtained. The SF36 is a generic QoL questionnaire that, through a 36-item short form survey, assesses eight health scale scores in relation to physical functioning, role-physical, physical pain, general health, vitality, social functioning, role-emotional, mental health)14. The SF36 scores estimated from the studied sample were compared to that reported in the Italian literature for normal hearing subjects and to that reported for hearing impaired subjects15. Finally, we studied the relationship between the results, in terms of speech perception with CI, and age at the first hearing aid fitting, progression of hearing loss, pre-operative PTA without hearing aids and pre-operative PTA with hearing aids in order to find any possible associations. The mean follow-up duration after surgery was 6.2 years, ranging from 1 to 13 years.

Statistical analysis

Statistical analysis was performed with the aim to investigate differences between the pre-operative and the post-operative speech perception abilities and health conditions of patients. The distribution of numeric variables was assessed by the Shapiro-Wilk W test for normality. Comparisons between pre- and post-CI intervention patients data were conducted using the Wilcoxon matched-pairs signed-ranks test for non-parametric distribution of continuous variables and the McNemar’s chi-squared test for categorical variables. The difference between paired data was considered statistically significant with a p < 0.05. Using the quantile regression model, we examined the relationship between the post implantation open-set speech recognition score and selected patient characteristics (covariates) such as as age at first hearing aid fitting, pre-operative PTA with hearing aids and progression of hearing loss, as well as the APHAB scales and SF36 scales for the 50th percentile. Compared with the traditional linear model, quantile regression is robust for departures from normality and heteroscedasticity assumptions in the response variable16. Statistical analyses have been performed using the statistical software Stata 12.1 (Stata Corp, College Station, Texas USA).

Results

The mean pre-operative hearing threshold in the implanted ear (pure tone audiometry - PTA between 0.5-1-2 KHz) was 111.08 dB (range 93 dB-125 dB). The mean pre-operative PTA in free field with hearing aids was 54.6 dB (range 31.6 dB-125 dB).

The mean pre-operative speech perception score was 15.7% (range 0-50). Before implantation, 7% of the patients were able to have telephone conversations.

After implantation, the mean pure tone audiometry (PTA between 0.5-1-2 KHz) in free field with the speech processor on was 34.7 dB (range 25-51.6 dB).

With regards to speech perception skills, the mean post-operative open-set words recognition score was 60% (range 0-100%) Two of 30 patients scored 0%. The improvement in terms of speech perception was statistically significant (p = 0.000).

After implantation, 60% of patients are able to have telephone conversations. The difference between the proportion of patients able to have telephone conversations before and after implantation was significant (p = 0.000). The most significant data, regarding subjective benefits after implantation, collected at the UPQ questionnaire are shown in Table II.

Note: *1 patient can have free conversations with unfamiliar people; **5 patients can have free conversations with unfamiliar people; *** 3% missing data pre- and postoperatively; ††13% missing pre-operative data, ‡1% missing data.
association was found between disyllabic word recognition scores and the Ease of Communication scale of the APHAB questionnaire (p = 0.030). Considering the other scales of the APHAB questionnaire and the eight scales of the SF36 questionnaires, we found no significant associations between each scale and disyllabic word recognition scores after CI intervention.

From the univariate quantile regression model, there are no evidence of statistically significant associations between post-implantation open-set speech recognition score and age at first hearing aid fitting, pre-operative PTA without hearing aids and pre-operative PTA with hearing aids (p > 0.05). Nevertheless, we found a significant association between post-implantation open-set speech recognition score and progression of hearing loss (p < 0.05).

Discussion

In the present paper, we report the results achieved in a group of 30 oralist prelingually deafened adults, submitted to CI.

Cochlear implantation in prelingual adult patients is still a true challenge since it requires a difficult decision making process for both clinicians and patients due to the uncertainty of the outcome and the risk of obtaining poor or no improvement in speech perception and stopping to use the implant; nevertheless, an increasing number of recent studies attest the efficacy of CI even in these cases, albeit with variable results. In a recent systematic review of the literature on effectiveness and cost-efficacy of CI in children and adults, we reported that cochlear implantation is both clinically- and cost-effective even in adults with prelingual deafness. In the sample herein, the results in terms of speech perception skills are quite satisfactory. After implantation, we recorded a significant improvement in open-set speech recognition scores: before implantation the mean open-set speech recognition score was 15.7% and after implantation it increased to 63.6%. Moreover, before surgery 7% of the patients were able to have telephone conversations, while after implantation 60% of patients were able, even if at various degrees of ability.

Most of the studies reporting post-implantation results in prelingual deafness have focused on speech perception results and only a few have dealt with patient satisfaction, subjective benefits and impact of CI on the quality of life. Studies investigating the impact of cochlear implantation on the quality of life in prelingually deaf adults found that, even when the results are poor in terms of speech perception abilities, participants reported satisfaction with the CI procedure. These observations suggest that measures other than speech perception test should be used to evaluate the benefit of a CI in this population, and therefore benefit and performance should be viewed as two separate outcomes.

In the present study, at the UPQ questionnaire we recorded an improvement in the ability to carry out some daily life activities such as the use of the telephone and the abil-

ity to listen to television and music. After implantation, 60% of the patients (n = 18) were able to have telephone conversations and 28% of these (n = 5) were able to have free telephone conversations even with unknown persons. In addition, 30% of patients were able to listen to television without reading subtitles, compared to only 3% before implantation. Furthermore, 77% of patients reported that after implantation the perception of music improved and 70% of patients indicated that with CI the perception of voice was more natural than with hearing aids (see Table I).

Concerning the results of the APHAB questionnaire, we recorded significant improvement after surgery in terms of median frequency of troubles while hearing in each of the four situations investigated by the questionnaire, such as ease of communication, background noise, reverberation and aversiveness (p < 0.05). Substantial improvements due to CI interventions were observed for ease of communications and background noise: median benefit 24.8 (IQR: 0-49.5, p = 0.003) and 16.2 (IQR: 3.7-40.5, p = 0.000).

With regards to the SF 36 questionnaire, our patients reported very high scores after CI intervention. The patient’s own quality of life perception after CI intervention was very similar to that of the normative sample of healthy Italian subjects, and even better for some aspects. Patients scored as well as the normative healthy sample for physical health, in terms of Physical Activity, Role and Physical Health and Physic Pain, and for mental health in terms of Role and Emotional Status. Implanted prelingually deafened patients did not experience limitations or pain due to their health condition in work or domestic activities nor problems resulting from emotional status. The general health and the mental health subjective perception was better in the sample of patients with CI than that of healthy patients. Implanted patients experienced lower scores for Vitality and Social Activities as compared to healthy subjects (median score: 70 (IQR: 60-85) versus 75 (IQR: 65-85) and 81.3 (IQR: 63-100) versus 87.5 (IQR: 75-100).

When comparing the scores recorded at SF 36 in our sample to the normative sample of Italian hearing impaired patients, our sample scored better than the normative sample in every aspect except for Role and Emotional State, where they achieved the same score (see Fig. 1).

The SF36 scores obtained in our sample of prelingually deafened patients have to be interpreted with much caution, as they are related to subjective evaluations on their own perception of quality of life. Moreover, the sample is small and in some subscales we recorded a high variability in answers. The comparison between our sample and the Italian normative one has some limitations due to the self-reported conditions identifying the Italian healthy group (mean age 34.8 years, age > 65 years 3.7%, female gender 46.8%) and the Italian hearing impaired group (mean age 63 years, age > 65 years 50.7%, female gender 45%).

According to literature data, even in the reported group, patients who did not achieve improvements in terms of open set speech recognition abilities reported substantial benefits in daily life activities and in the QoL.

It is well known that the outcome after CI in prelingually deafened adults is quite variable and is best shown in the work by Klop et al (2007) 8. This is likely to be related to the wide variability of the characteristics of patients. Post-implantation benefits both in adults and children is related to several individual factors, and this is mostly true in the case of pre-lingually deafened adults. Pre-operative factors that seem to make a significant contribution to post-operative hearing performance are age at onset of hearing loss and at first hearing aid fitting, speech perception performance with hearing aids 6 7 11 12 21, residual hearing 21, communication mode 21, type of rehabilitation, educational environment 21, motivation and psychological aspects 21 6 7 11 12.

Moreover, Dijkhuizen et al. in 2011 reported that speech intelligibility is predictive of post-implantation hearing results in a group of prelingually deafened adults, using a specifically developed test battery 22 and in a recently published paper has confirmed this 23.

With regards to predictive factors in prelingually deafened adult patients, it has to be underscored that prelingually deafened adults have some peculiar aspects, as they have never experienced normal hearing in life and
thus their neural system lacks the spatial and structural organisation for auditory processing. The literature suggests that the colonisation of the auditory cortex by other sensory modalities is the main limiting factor in post-implantation performance, and not the pathological degenerative changes of the auditory nerve, cochlear nucleus, or auditory midbrain \(^{11,12}\). Consequently the educational programs that stress oral communication as the preferred educational modality could potentially reduce the cortical colonisation of the central speech and language processing centres, and consequently the use of oral communication should be an important candidacy criterion in cochlear implantation of patients with long-term prelingual deafness. Moreover, some recent studies have explored the role of early auditory input on CI performance in prelingually deafened adults, and it was concluded that the availability of effective auditory input in early life may be the fundamental factor underlying the potential for speech perception with a CI in later life \(^{11,12,7}\).

Considering the sample herein reported, a relatively high percentage of the patients (63%) experienced a progression of hearing loss. These patients presumably had a better auditory input early in life. We believe that this factor, associated with oralism as an exclusive mode of rehabilitation, played an important role in achieving satisfactory results reported, also in terms of open-set speech recognition abilities and consequently in the ability to have telephone conversations. In this regard, we recorded a statistically significant correlation between post-operative dysillabic word recognition score and progression of hearing loss (p < 0.05) in our sample; nevertheless, we did not find a significant correlation between post-operative results and pre-implant hearing threshold either with or without hearing aids and age of first hearing aid fitting.

**Conclusions**

In conclusion, our results demonstrate that cochlear implantation is an effective option for prelingually deafened adult patients. In accordance with the literature data, the results reported herein are quite variable but generally satisfactory, both in terms of improvement of speech perception abilities and in terms of improvement of the quality of life and patients’ perception of their disability. Indeed, some individual factors significantly affect the results, and among these effective auditory input in early life and oralist rehabilitation mode seem to be the fundamental factors underlying the potential for speech perception with a CI later in life \(^{6,7,11,12,21}\). In this regard, we found a significant correlation between the progression of hearing loss and post-operative results. Such patients had experienced a relatively good and effective auditory input early in life, and this allowed their auditory cortex to develop properly, which in turn allowed them to gain satisfactory results in terms of speech perception after implantation.

Therefore, the indications to CI and prognostic factors must be discussed on a case by case basis, taking into account mainly the progression of hearing loss, hearing aid use and results before implantation, rehabilitation mode, motivations and psychological aspects, and it is important to perform accurate counselling to provide patients with realistic expectations.

SUMMARY

Endolymphatic sac tumour (ELST) is infrequent, as emerges from small series reported in the literature. It is a slow-growing malignancy with local aggressiveness and a low risk of distant metastases. It is often misdiagnosed because of the late onset of symptoms and difficulty in obtaining a biopsy. Its frequency is higher in von Hippel-Lindau (VHL) disease (a genetic systemic syndrome involving multiple tumours), with a prevalence of around 25%. The diagnosis is based on radiology, with specific patterns on contrast-enhanced MRI and typical petrous bone erosion on bone CT scan. Our experience of ELST in the years between 2012-2015 concerns 7 cases, one of which was bilateral, in patients with VHL disease. Four of the 7 patients underwent 5 surgical procedures at our institution. Each case is described in detail, including clinical symptoms, and the intervals between symptom onset, diagnosis and therapy. Postoperative morbidity was low after early surgery on small tumours, whereas extensive surgery for large tumours was associated with loss of cranial nerve function (especially VII, IX, X). The critical sites coinciding with loss of neurological function were the fallopian canal, jugular foramen, petrous apex and intradural extension into the posterior cranial fossa. Early surgery on small ELST is advocated for patients with VHL disease, in whom screening enables a prompt diagnosis and consequently good prognosis.

KEY WORDS: Endolymphatic sac tumour (ELST) • Cerebellopontine angle (CPA) tumour • Temporal bone tumour • Von Hippel-Lindau disease (VHL) • Low-grade adenocarcinoma

Introduction

Endolymphatic sac tumour (ELST) is a rare malignancy originating from the endolymphatic system 1-4. Embryologically, the sac derives from the neuroectoderm and is located on the posteromedial surface of the temporal bone. ELST was historically classified as primary adenomatous tumour of the temporal bone, and was not clearly defined until the end of the 1980s when Gaffey et al. distinguished
functional impairment depends on the sites and subsites of tissue destruction has occurred; the severity of the related symptoms is relatively asymptomatic until significant surrounding tissue swelling or endolymphatic hydrops irrespective of tumour size. When part of the VHL syndrome, the tumour has a relentless and more aggressive growth, and its onset is at a younger age than in sporadic cases. When early diagnosis is followed by early surgery, hearing loss is the price to pay in terms of surgical morbidity (though there are some reports in the literature of cases in which hearing was preserved). The origin of the tumour being well-established, if left untreated, its growth can involve critical sites such as the fallopian canal, jugular foramen and cerebellopontine angle, and subsequent surgical morbidity is severe.

Our experience of ELST in VHL in the years between 2012-2015 is described herein, together with a discussion of the main diagnostic and therapeutic controversies of this infrequent disease.

Materials and methods
This was a retrospective analysis on all cases of ELST managed at the Department of Otolaryngology of Padua University Hospital between January 2012 and September 2015.

We reviewed the clinical, audiological, radiological, surgical and pathological records of 7 consecutive ELST patients. Four patients underwent resection with 5 surgical procedures (one patient had a bilateral procedure performed elsewhere, then came to our attention with bilateral residual disease and was treated with further surgery, and is awaiting a cochlear implant). The other 3 cases were not surgically treated and, up to now, managed differently.

This study included only adult patients with a clinical or genetic diagnosis of VHL syndrome. All patients were assessed at the Department for Hereditary Tumours and Oncological Endocrinology of the Istituto Oncologico Veneto. VHL mutations were ascertained from peripheral blood samples using Southern blotting, fluorescence in situ hybridization and complete gene sequencing.

Common clinical manifestations included hearing loss, tinnitus, vertigo, dizziness, aural fullness, balance disturbances, ear pain and facial nerve palsy. Large tumours growing posteromedially caused symptoms secondary to cerebellopontine angle invasion, or lower cranial nerve palsy due to jugular foramen invasion.

Audiological examination was conducted with pure tone audiometry (air and bone conduction thresholds) and vo-
Endolymphatic sac tumour in von Hippel-Lindau disease: management strategies

cal audiometry (speech reception thresholds and discrimination loss); the four-frequency pure-tone average based on air conduction thresholds at 0.5, 1, 2 and 4 kHz was used to judge the degree of hearing loss.

Facial nerve function was measured according to the House-Brackman scale, and was tested by electromyography of the cranial district. Subjects were assessed on unenhanced high-resolution computed tomography (CT) scans and contrast-enhanced high-resolution magnetic resonance imaging (MRI) of the temporal bone; diagnostic magnetic resonance sequences analysed were T1-weighted (with and without contrast), T2-weighted, and fluid attenuated inversion recovery (FLAIR) (with and without contrast).

Radiological findings typically included: retrolabyrinthine involvement with focal erosion of the posterior wall of the petrous bone, intratumoural calcification with calcified spicules on CT scan, hyperintense focal signals on T1-weighted (unenhanced) MRI and heterogeneous signals on T2-weighted MRI.

Surgical specimens of resected tumours were routinely stained with haematoxylin and eosin for immunohistochemical analysis.

Surgery was performed by the same team of ENT surgeons. During the follow-up, patients underwent clinical/audiological examination every 6 months and MRI annually. All patients gave their verbal consent to participation in the study.

Results

Our series consisted of 7 patients, 5 females and 2 males, aged 35-62 years (mean 42.7). Table I lists the clinical and audiological examinations carried out on all patients, and Table II the surgical and postoperative details for patients who underwent skull-base surgery. Four of the 7 patients underwent surgery with radical intent, while 3 have yet to be treated surgically. The 3 cases who were not yet operated on, are detailed herein. In VHL syndrome, the presence of concomitant cerebral, cerebellar or brainstem tumours with impending risk or neurologic sequelae involved the necessity to postpone surgical treatment of ELST in favour of other more urgent conditions.

One 36-year-old woman (patient 6) had a bilateral neurosurgical procedure elsewhere and presented with bilateral residual disease involving the petrous bone and bilateral deafness. Transpetrous revision surgery and cochlear implant was scheduled at our institution, but at the time of writing the latter had been postponed due to the concomitant need to operate on a cerebellar haemangioblastoma. One patient who was totally deaf on the affected side (patient 5) had undergone surgery via a neurosurgical approach 10 years earlier, at the age of 30, followed by postoperative radiotherapy (60 Gy multifractioned), and had residual disease in the petrous bone, which had since been growing. A period of at least 10 years was judged necessary before any new surgical treatment could be performed on an irradiated petrous bone to prevent infectious sequelae, such as osteonecrosis or osteomyelitis. The patient will be a candidate for revision surgery with translabyrinthine approach after 10 years have elapsed.

Patient 7 presented with a tumour involving the petrous bone, the jugular foramen area and the cerebellopontine angle, having recently been treated for a cerebellar haemangioblastoma on the same side, via a neurosurgical approach. ELST was not properly identified at radiology,

Abbreviations: SN, sensorineural; FN, facial nerve; HB, House-Brackmann; Hbs, haemangioblastoma; ret., retinal; RCC, renal clear cell carcinoma; Pheo, pheochromocytoma
and was initially considered an extension of the haemangio/ 
gioblastoma, but intraoperative findings confirmed the di-
agnostic suspicion of concomitant, aggressive ELST origi-
nating from the petrous bone. The patient experienced 
postoperative IX to XII nerve palsy, which was given time 
to compensate before planning another procedure on the 
jugular foramen that would involve a definitive paralysis 
of the nerves.

On retrospective review of our ELST patients, delays emerged 
between symptom onset and diagnosis, and between diagnosis 
and treatment. The mean delay between diagnosis and surgery 
was 33 months (range: 5 months to 8 years).

In patients 1 (Fig. 1) and 2, the sites of tumour involve-
ment were the endolymphatic sac, labyrinth and dura of 
the posterior fossa; in patients 3 and 4 (Fig. 2), who had 
the greatest diagnostic and therapeutic delays, the tumour 
extended to and infiltrated the jugular bulb and infra-lab-
yrinthine area.

No perioperative or postoperative complications were 
recorded. Postoperatively, the facial nerve was intact in 
3 of the 4 surgically-treated cases; the fourth (patient 4) 
received a graft after intraoperative sacrifice of the facial 
nerve due to tumour infiltration. All surgical patients are 
alive and disease-free at mean follow-up of 41.5 months 
(range 36-50). No adjuvant therapy was administered.

Discussion

ELST is a locally aggressive tumour originating in the 
endolymphatic sac on the posterior border of the pe-
trous ridge. Its slow but relentless growth into the petrous 
bone and then into the cerebellopontine angle and mid-
dle cranial fossa can involve the surrounding neurovas-
cular structures, such as the carotid artery and the cranial 
nerves from VII to XII. The VI cranial nerve involves the 
tumour’s extension into the petrous apex, which is infre-
quent but possible.

Before being reclassified, ELST was underestimated and 
for years it was often misinterpreted as paraganglioma, 
metastatic renal cell carcinoma, choroid plexus papill-
loma, ceruminous gland adenocarcinoma, or aggressive 
papillary tumour. Its diagnosis is radiological, and it has 
quite a specific pattern of presentation: a retrolabyrinthine 
location with focal erosion of the posterior wall of the 
petrous bone, intratumoural calcification with calcified 
spicules on CT scan, hyperintense focal signals on T1-
weighted (unenhanced) MRI scan, markedly heterogeneous 
enhancement after gadolinium and heterogeneous 
signal on T2-weighted sequences.

It is easier to diagnose in small lesions, when the tumour’s origin is still pathognomonic. On the other hand, when the disease involves the jugular foramen or the intradural compartment, extensive bony destruction prevents the typical origin of the tumour from being established. Further investigations might be useful to rule out intracranial vessel involvement in order to plan safe surgery. Arteriography may give information about carotid artery infiltration, or when part of the approach or in case of disruption or planned sacrifice: in such cases, a balloon occlusion test may be added. In our series, it was never necessary.

It is essential to consider the differential diagnosis, although in VHL patients ELTS may be a presenting sign of the syndrome.

Treatment of ELTS demands extensive surgery with adequate bone removal around the area of macroscopically evident tumour. Lateral skull base approaches each have their intrinsic morbidity, but in principle, morbidity is directly proportional to the extension of the tumour. Microsurgical approaches through the temporal bone are directed to the site of origin of ELST along the petrous ridge and the surrounding subsites of tumour involvement, and may be combined if required.

A transmastoid-retrolabyrinthine approach is for a small endolymphatic tumour, with no extension in the surrounding subsites. The translabyrinthine approach is for larger tumours, with poor hearing and extending through the labyrinth and/or intradurally in the posterior fossa. The involvement of the middle ear is better managed through a petrosectomy, lateral or subtotal. When ELST extends to the jugular foramen, POTS allows good and safe exposure of the infralabyrinthine and jugular foramen area. Similarly, involvement of the petrous apex or the middle cranial fossa, is managed by combining a transmastoid-transpetrous approach with a subtemporal/middle cranial fossa approach. The pure retrosigmoid approach, directed to the intradural extension of the tumour in the posterior fossa, may be not large enough to allow extensive drilling of the petrous bone around the site of origin of ELST. Small tumours, as seen when ELTS is diagnosed early and treated promptly, entail hearing loss but no further morbidity. When hearing is already impaired, there can be no doubt about the advisability of surgery for early le-
sions. When hearing is unaffected (an infrequent situation that may be encountered on screening or in the case of incidentally-found tumours), it is nonetheless at risk. As a rule, it is difficult to ensure the removal of even a very small tumour within the endolymphatic sac and vestibular aqueduct without hearing loss or impairment, although some experiences of hearing preservation after the resection of very small tumours have been described 12, 19, 29. Hearing preservation after early surgery for very small tumours seems a distinctly sporadic event, and should not (in our opinion) be presented as a likely outcome when proposing surgery to patients. Any disruption of the endolymphatic sac and vestibular aqueduct can be a cause of hearing loss, per se, even in patients with very small tumours.

If the tumour is left untreated and reaches surrounding subsites like the fallopian canal with the facial nerve, jugular foramen area, petrous apex and intradural compartment of the cerebello-pontine angle and middle cranial fossa, the related surgical morbidity is a completely different story. Bambakidis 21 proposed a classification of ELST based on size and sites of extension, but does not reflect the problems of the related surgical morbidity, since this is already evident for stage I tumours. Early diagnosis and prompt therapy are key to avoid unavoidable foreseeable tumour extension into critical sites. When aggressive and extensive surgery is required, the prognosis is unfavourably affected because of the related surgical morbidity, and radicality is rarely achievable even with very extensive surgery.

The effectiveness of radiotherapy (stereotactic or fractionated) is still unclear, without any evident benefit in long-term prognosis for patients 10. Postoperative radiotherapy in subtotal resection may give some beneficial results, but with a risk of relapse > 50% 9. Since ELST can be a facet of VHL disease, accurate screening should be considered to detect the tumour early and thus offer patients early surgery with a good prognosis, good long-term disease-free survival rates and limited treatment-related morbidity 30. Delaying treatment is not uncommon in patients with the syndromic form of ELST, due to the complexity of VHL disease, with multiple tumour localisations in other body districts that often require prompt surgery 10. In principle, awareness that early surgery for small tumours is associated with a low impact in terms of morbidity and a prompt recovery after the procedure should enable the treatment of ELTS to be scheduled appropriately in the frame of VHL.

Clinical-radiological screening in VHL populations at risk of ELST may favourably affect prognosis, providing that early diagnosis is followed by prompt therapy. When the tumour is bilateral – a situation seen in 30% of syndromic patients 3 and, to the best of our knowledge, never reported in sporadic cases – there is the problem of bilateral deafness as the natural outcome of the evolution of the disease. The mechanisms behind it are direct invasion of the inner ear, endolymphatic hydrops that mimic Meniere’s disease 31, and intralabyrinthine hemorrhage (even in small tumours), which is responsible for sudden sensorineural hearing loss 32.

Early rehabilitation with a cochlear implant may be the solution, but the tumour has to be resected before it reaches and destroys the cochlea as well as the posterior labyrinth. Though not involved directly, damage to the posterior labyrinth (vestibule or/and semicircular canals) and surgical trauma associated with tumour removal may cause ossification in the cochlea and prevent its proper functioning, or even the insertion of the cochlear implant 33. There seem to be sporadic cases of hearing preservation after early surgery for very small tumours, but it would be wrong (in our opinion) to consider sparing natural hearing as one of the goals of any proactive surgery. Disruption of the endolymphatic sac and vestibular aqueduct suffices in itself to cause hearing loss, even in patients with very small tumours.

Conclusions

ELTS is infrequent and usually misdiagnosed, but screening for this cancer can be routinely performed in VHL patients. The most appropriate timing of its treatment should be established for the purpose of achieving a low morbidity by performing early surgery on a small tumour. Hearing is always at risk when surgery is performed for ELST, but preserved normal hearing in a patient with detectable ELST is unusual; hearing loss is generally identified already at diagnosis, even in the case of small tumours. There have been some sporadic reports of hearing being preserved after surgery for ELTS 19, 29. A ‘wait-and-see’ strategy can only be a temporary solution for ELTS in VHL disease to enable the treatment of multiple tumours to be planned. The slow, but relentless growth of ELTS – especially in syndromic cases – leads to unfavourable outcomes once critical structures have been affected, because they cannot be spared, meaning that postoperative morbidity is significant and long-term disease control rates are low.

Screening VHL patients for the early detection of ELST is very important in order to ensure the most favourable timing of radical surgery and the least possible morbidity.

SUMMARY

The aim of this study was to assess the function of the utricle and horizontal semicircular canals in patients with type 2 diabetes mellitus receiving primary health care, with/without a history of falls. 101 patients with type 2 diabetes mellitus, 34 to 84 years old (26 with and 75 without a history of falls) and 51 healthy volunteers (40-83 years old) accepted to participate. They denied having a history of dizziness, vertigo, unsteadiness, hearing loss, or neurological disorders. None of them were seeking care due to sensory or balance decline. After a clinical evaluation and report of symptoms related to balance using a standardised questionnaire, lateral canal function was assessed by sinusoidal rotation at 0.16 Hz and 1.28 Hz (60°/sec peak velocity), otolith function was assessed by static visual vertical (average of 10 trials) and dynamic visual vertical during unilateral centrifugation (300°/sec at 3.5 cm) and static posturography was performed on hard/soft surface with eyes open/closed. Compared to healthy volunteers, patients showed decreased responses to unilateral centrifugation, but similar responses to horizontal canal stimuli (independently of age, peripheral neuropathy or a history of falls) (ANCoVA p < 0.05) and a larger sway area with a lengthier sway path. Compared to patients with no falls, patients with falls had a higher female/male ratio and a higher frequency of score ≥ 4 on the questionnaire of symptoms related to balance, but similar age, body mass index and frequency of peripheral neuropathy. In patients with type 2 diabetes mellitus, receiving primary healthcare who are not seeking care due to sensory or balance decline, utricular function may be impaired even in the absence of horizontal canal dysfunction or a history of falls.

KEY WORDS: Diabetes mellitus • Vestibular function • Falls

Introduction

To maintain balance, any perturbation of stance must be opposed by coordinated motor responses, requiring sensory information from multiple sources, including somatosensory, vestibular and visual inputs. Evidence has shown that individuals with somatosensory or vestibular deficit are limited in their ability to re-weight postural sensory inputs 1-2, with the risk of falling. Falls occur as a result of complex interactions between intrinsic (demographic and biological factors) and extrinsic...
Utricular hypofunction in type 2 diabetes mellitus

Factors (environmental and behavioural factors) 1 Diabetest mellitus is an independent risk factor for falling, particularly in the elderly 1,5. Patients with diabetes mellitus may have sensory deficits as well as unrecognised postural instability 6-9. In this group of patients, the frequency may have increased latency and decreased amplitude of the short latency vestibular evoked potentials in response to linear acceleration 10, as well as a high incidence of osmophilic inclusion bodies in the saccular and utricular nerves, with disrupted myelin-sheath lamellae 11. Accordingly, in patients with type 2 diabetes mellitus vestibular dysfunction on clinical tests has been observed 12-14. However, studies evaluating the otoconial function of patients with type 2 diabetes mellitus are scarce, even more so in patients receiving primary health care. In a recent study, otoconial organ impairment by cervical and ocular vestibular-evoked myogenic potentials was recognised in 50% of adult patients with type 2 diabetes mellitus (saccular, utricular or both organs) 14.

The aim of this study was to assess the function of the utricular macula and the horizontal semicircular canals, as well as postural stability of patients with type 2 diabetes mellitus are scarce, even more so in patients receiving primary health care. In a recent study, otoconial organ impairment by cervical and ocular vestibular-evoked myogenic potentials was recognised in 50% of adult patients with type 2 diabetes mellitus (saccular, utricular or both organs) 14.

The significance level was set at 0.05 for two tails. According to the occurrence of falls within the previous year, by the definition of the World Health Organization 3, patients were classified in two groups (Table I):

I. 75 patients with no history of falls (34 to 84 years old).
II. 26 patients with a history of falls (42 to 79 years old).

After clinical evaluation, including bed-side head shaking and positional tests, all participants replied to a self-administered questionnaire of symptoms related to balance, which was previously validated (Kurder Richardson 20 = 0.75, intra-class rank correlation coefficient = 0.9) 15. The questionnaire includes nine items to report each of the balance symptoms described in Fig. 1, with yes/no answers. A “no” response was scored 0 points and a “yes” response was scored 1 point, except for vertigo which was scored 2 points; frequent falls were considered when occurring at least once per month, and frequent stumbles when occurring at least once per week. The total score is calculated by adding all the points (range 0 to 10); a score higher than 3 can be related to balance disorders 15.

Vestibular function was evaluated by sinusoidal rotation at 0.16 Hz and at 1.28 Hz (60°/sec peak velocity), static visual vertical (average of 10 trials) and dynamic visual vertical during unilateral centrifugation (300°/sec at 3.5 cm) (I-Portal-NOCT-Professional, Neuro-Kinetics, Pittsburgh). For centrifugation, the chair was accelerated to 300°/sec in 60 sec; after 60 sec of full speed rotation the chair moved from the center position to the right in 30 sec, while in offset position the chair dwell for 60 sec, then it moved from the right position to the center in 30 sec, while in the center position it dwell for 60 sec, then it moved from the center position to the left in 30 sec, while in the offset position it dwell for 60 sec, then it moved from the left position to the center in 30 sec, and finally decelerated from 300°/sec to 0°/s in 60 sec. Postural stability was evaluated using static posturography on hard and soft surface, with the eyes either open or closed (Posturolab 40/16, Cedex). In patients with diabetes, peripheral neuropathy was evaluated at first by the Michigan Diabetic Neuropathy Score 16 and the Semmes-Weinstein 10 g monofilament, when any of these two instruments was positive, nerve conduction studies were performed on the tibial and sural nerves (Spirit, Nicolet, Madison, U.S.A.) 17.

Bivariate analysis was performed using “t” test (either for proportions or for means, accordingly), and multivariate analysis was performed using multiple regression and analysis of covariance (Statistica, Statsoft Inc., Tulsa). The significance level was set at 0.05 for two tails.

Materials and methods

After approval of the research protocol by the Research and Ethics Committees of the Institution, informed consent was obtained from all participants and the study was performed according to the Declaration of Helsinki and amendments. A total of 101 consecutive patients with type 2 diabetes mellitus, who met selection criteria (age range 34 to 84 years, mean 60.3 ± 9.8; 27 men; BMI 29.1 ± 4.5) and 51 age-matched healthy volunteers (age range 40 to 83 years, 56.5 ± 6.8; 22 men; BMI 28.4 ± 4.8) participated in the study. The proportion of males was lower in the patient group than in the control group (26.7% versus 43%, p = 0.04). One additional patient accepted to participate but declined to complete the study protocol due to difficulty to attend an appointment. All participants denied having a history and having no medical record of otology, neurology, psychiatry, or orthopaedic disorders, postural hypotension, or exposure to ototoxic medication or unsafe noise levels. All had similar access to health care, but none were seeking it due to sensory or balance deterioration. Patients were receiving primary health care for diabetes and the most frequent medication was metformin (76.4%, 95% C.I. 68.4-84.4%).

Results

In patients with diabetes mellitus, comparison between those with/without falls showed a similar age and BMI as well as a similar frequency of peripheral neuropathy, retinopathy and other clinical characteristics (Table I).
However, patients with falls had a higher female/male ratio and were diagnosed later in life than patients with no falls (Table I).

Patients and controls had a similar gain to sinusoidal rotation at both 0.16 Hz and 1.28 Hz (Table II). However, compared to controls, patients with diabetes, either with or without a history of falls, showed an increased deviation of the static visual vertical and decreased responses to unilateral centrifugation (p < 0.01) (Fig. 2, Table II).

Multiple regression analysis showed a significant contribution to falls from the gender (beta 0.16, 95% C.I. -0.02-0.35) (R = 0.35, p = 0.008) and the total score of symptoms related to balance (beta 0.20, 95% C.I. 0.1-39), but no other significant relationships were observed. The frequency of patients with a total score suggesting a balance disorder (≥ 4) was almost twice that in patients with falls (57.7%, 95% C.I. 38.7-76.7%) than in patients with no falls (32.5%, 95% C.I. 23.3-42.7%) (“t” test for proportions, p ≤ 0.05). Among the items, a significant difference between the groups was observed on a larger proportion of patients with falls reporting frequent stumbles (Fig. 1) (“t” test for proportions, p ≤ 0.05), while in the two groups the most frequent symptoms were instability when changing posture and when moving the head rapidly (Fig. 1).

Compared to healthy controls, during static posturography patients with diabetes showed a larger area of sway while standing with the eyes open either on hard or soft surface, which was accompanied by a lengthier sway path (Table III).

Among patients with diabetes, the Romberg index, either on hard or soft surface, showed no significant difference

between patients with/without falls (p > 0.05), and covariance analysis did not show any other significant relationship with the clinical characteristics of the patients. However, comparison between those with/without peripheral neuropathy showed that patients with no falls but neuropathy had a trend for a larger area of sway, with no lengthier sway path, while in patients with falls there was no consistent difference between those with or without neuropathy (Table III).

Discussion
Evaluation of patients with type 2 diabetes mellitus receiving primary health care who were not seeking care for balance disorders, compared to healthy volunteers, showed decreased responses to utricular stimulation by unilateral centrifugation, even when horizontal canal function at 0.16 Hz and 1.28 Hz was preserved, and a larger area of sway with a lengthier sway path on static posturography. These results suggest that, in patients with diabetes mellitus receiving primary health care an underlying otolith vestibular dysfunction may contribute to postural instability, which could enhance the effect of other sensory deficits and in turn may add to the risk factors for balance decline.

The finding of decreased utricular responses to unilateral centrifugation in patients with type 2 diabetes mellitus, even when horizontal canal function was preserved, is consistent with the dissociation between the responses to cervical and ocular vestibular-evoked myogenic potentials and head thrust dynamic visual acuity in all canal planes recently reported in patients with diabetes. Although in that study the head thrust dynamic visual acuity testing showed semicircular canal dysfunction in at least one plane in 70% of patients, participants were all 50 years of age and older with ≥ 10-year history of type 2 diabetes. The different responses of the two end organs, otoliths and semicircular canals, in early stages of diabetes mellitus could be related to their metabolic and vascular characteristics. In murine models, evaluation of the local metabolic rate of glucose utilisation has shown similar results for the utricle and saccule, which were significantly higher than that for the superior, posterior, or lateral canal ampulla. Compared to the posterior canal ampulla, the rat utricular macula is similar with respect to neuroepithelial volume, capillary surface area and blood flow, but the capillary diameter is smaller and the capillary length is greater. This is consistent with the findings in rats with long-term experimental diabetes of increased capillary diameters along with increased vascularisation of the saccule, suggesting greater stress on the capillary wall. In addition, the maculae of neither animal models nor human beings have shown microangiopathy, even if loss of type I hair cells has been described, while evidence supports that dysregulated energy metabolism could also have a role in the vestibular dysfunction due to diabetes mellitus in the context of insulin signaling networks.

Vestibular dysfunction is a significant differential diagnosis in patients who have unexpected falls, and in patients with peripheral neuropathy related to diabetes balance recovery after peripheral vestibular disease may be compromised. However, in this study, the evidence of utricular dysfunction in both groups of patients (with/without falls), with a similar frequency of peripheral neuropathy and a low frequency of retinopathy, did not allow the assessment of the interaction between sensory deficits. Likewise, the low frequency of insulin use and similar glycated haemoglobin levels in the two groups (Table I) did not allow an adequate assessment of possible influence of these variables on vestibular function and postural control. Although it is already known that during quiet stance patients with diabetes and peripheral neuropathy sway more...
Table III. Mean and 95% confidence interval of the mean of the length of sway and area of sway of 101 patients with type 2 diabetes mellitus with/without falls and with/without peripheral neuropathy, and 51 age-matched volunteers without diabetes mellitus.

than controls and even more so if their visual or vestibular systems are perturbed. In this study, patients with diabetes, compared to healthy controls, showed a larger area of sway and a lengthier sway path. However, those with no history of falls but neuropathy had a trend for a larger area of sway, while those with falls, either with or without neuropathy, showed more variability on their sway path. This finding supports that peripheral neuropathy may interact with other sensory impairments and factors related to postural coordination underlying balance decline. In this study, the sample size as well as the low frequency of retinopathy in patients with/without a history of falls may preclude further discussion on the interaction among sensory deficiencies. Among patients with diabetes, a gender influence on falling was evident. The association between female gender and higher risk of falls has been described previously. This finding could be at least partially related to muscle strength. Age-related decline in muscle quality is more pronounced in women than men, as well as age related hallux plantar-flexion strength decrease.

The results of this study should be interpreted in the context of its limitations. Since utricular hypofunction was evident in patients with/without falls, and no additional tests were performed, its contribution to postural instability cannot be assessed adequately. Since the evaluation of the occurrence of falls was by self-report, inaccuracy cannot be excluded. In this study, patients were recruited in a primary health care setting, with a low frequency of both complications and polypharmacy, with no history of otologic, neurologic, or orthopaedic disorders. Thus, in patients with more physical impairments the results may be different. According to the cross-sectional design of the study, the findings cannot exclude that patients may develop other vestibular dysfunction in the future. Longitudinal studies are needed to assess the development of the vestibular damage related to diabetes mellitus and its influence on postural control.

Conclusions
In conclusion, in patients with type 2 diabetes mellitus receiving primary health care, who are not seeking medical care due to sensory or balance decline, utricular function may be impaired even in the absence of semicircular canal dysfunction or a history of falls, and the occurrence of falls may not be independently related to vestibular function.

SUMMARY

The mainstay of treatment of craniofacial dysplasia (CFD) remains surgery once clinical observation has been excluded. Nevertheless, disagreement remains about the type of surgical intervention (remodelling versus radical resection). The aim of this paper is to present our experience until 2013 comparing CFD management between 1980 and 2002 and between 2003 and 2013 and to propose our surgical algorithm. From January 2003 to December 2013, 41 new patients (18 males and 23 females) with histologically demonstrated CFD presented to our Department. Data were compared with those of 95 patients observed and/or treated between 1980 and 2002. Considering the last period, we noted that observation (26/41 patients) was the most used method; radical resection was performed in most cases (8/15 patients), but in proportion the numbers of patients undergoing bone shaving has increased (6% between 1980 and 2002 vs 15% between 2003 and 2013), while a decrease in the number of patients undergoing excision was seen (63% between 1980 and 2002 vs. 19% between 2003 and 2013). On this basis, we believe that radical resection is the only technique to obtain resolution of fibrous dysplasia. Wait-and-see is indicated in case of stable lesions. Reconstructive techniques allow obtaining adequate aesthetical and functional results; nevertheless, in most cases adjunctive surgical refinements are required and recovery time is higher than with surgical shaving, so that most patients prefer to perform remodelling. Nevertheless, in case of aggressive lesions radical resection is mandatory, except in paediatric patients with residual large defects in which it can be acceptable to try to resolve symptoms via bone shaving, reserving more aggressive treatments in case of relapse or after skeletal maturity.

RIASSUNTO

Nonostante la chirurgia rimanga l’opzione di scelta nel trattamento della displasia cranio-facciale (CFD) una volta che l’osservazione clinica sia stata esclusa, resta controverso il tipo di intervento (rimodellamento contro resezione radicale). Lo scopo di questo lavoro è di rivedere criticamente la nostra esperienza fino al 2013 confrontando la gestione CFD tra il 1980 e il 2002 e tra il 2003 e il 2013 e di proporre il nostro algoritmo chirurgico. Dal gennaio 2003 al dicembre 2013, 41 nuovi pazienti (18 maschi e 23 femmine) con diagnosi di CFD sono stati considerati. I dati sono stati confrontati con quelli di 95 pazienti che sono stati osservati e/o trattati tra il 1980 e il 2002. Considerando l’ultimo periodo abbiamo notato che l’osservazione clinica (26/41 paz) è stato il metodo più utilizzato; una resezione radicale è stata eseguita in molti casi (8/15 paz), ma in proporzione il numero di pazienti sottoposti a rimodellamento è aumentato (6% vs 15%), mentre è stato osservato una diminuzione del numero di paz sottoposti escissione (63% vs 19%). Su queste basi, riteniamo che la resezione radicale rimanga l’unica tecnica per ottenere la risoluzione della displasia fibrosa. L’osservazione clinica è indicata in caso di lesioni stabili. Le moderne tecniche ricostruttive consentono di ottenere adeguati risultati estetici e funzionali in caso di resezione radicale; tuttavia, nella maggior parte dei casi si rendono necessarie ulteriori procedure ed i tempi di recupero sono superiori, cosicché la maggior parte dei pazienti preferiscono eseguire il rimodellamento. Nonostante tutto, in caso di lesioni aggressive la resezione radicale è mandatorria, tranne che in pazienti pediatrici in cui tale intervento comporterebbe estesi difetti residui: in tali casi può essere accettabile effettuare un rimodellamento riservando trattamenti più demolitivi in caso di recidiva o dopo la maturità scheletrica.

Introduction

Fibrous dysplasia (FD) is a non-malignant bone lesion characterized by replacement of normal bone with fibrous connective tissue. It was first described by Von Recklinghausen in 1981 as “osteitis fibrosa generalisata” 1,2. In 1938, Lichtenstein and Jaffe introduced the term “fibrous dysplasia”, differentiating between the monostotic and polyostotic types (MFD and PFD, respectively) 3. The McCune-Albright syndrome (MAS) was described in 1937 4,5; in these cases, the polyostotic form is associated with precocious puberty and areas of cutaneous pigmentation (café au lait spots). The term craniofacial dysplasia (CFD) has been introduced to describe forms arising in the contiguous bones of the cranium and facial skeleton; therefore, it cannot be defined as either a monostotic or polyostotic type 6. In cases of MFD, the zygomatic-maxillary complex is reported to be the region most commonly involved. In cases of PFD and MAS, the anterior cranial base is involved in the disease in more than 95% of cases 7,8. Even if medical therapy has a role in the management of symptoms, the mainstay of treatment remains surgery (radical or conservative). Clinical observation is recommended in cases of asymptomatic, slow-growing lesions that do not compromise the quality of life.

We present our experience in 95 patients affected by FD involving craniofacial bones (1980-2002). Among these, we performed surgery in 68 cases. We present an update of our experience and propose our surgical algorithm in which we critically review our experience prior to 2013, and then compare FD management between 1980-2002 and 2003-2013.

Materials and methods

From January 2003 to December 2013, 41 new patients (18 males and 23 females) with histologically demonstrated fibrous dysplasia located in the cranio-maxillofacial area presented to our department. Medium follow-up was 51 months (range: 9-108 months). The average patient age was 29 years (range: 8-72 years). In 35 cases (85%), patients presented with MFD as specified in our previous study; forms affecting two contiguous segments of bone were classified as monostotic, and thus, monostotic should be understood as meaning monofocal. Five patients (12%) had PFD, while only one patient (3%) was diagnosed with MAS. Considering the two periods examined (1980-2002 versus 2003-2013), differences between distribution of the FD type in the patient populations are illustrated in Figure 1A.

Results

Among these 41 patients, 15 (36.5%) underwent surgery. When considering 95 patients that presented to our department between 1980 and 2002, a higher percentage (71.2%) were surgically treated (68 patients). Management of FD according to the patients’ group is illustrated in Figure 1B. Observation (26/41 patients) was the most widely used method in the last 10 years. This group consisted of 17 females and nine males with a median age of 31.5 years (range: 8-72). Of particular interest was that nine paediatric patients (34.6%) were present. In 22/26 patients, MFD was observed. Specific data are reported in Table I. None of these patients received treatment, since stable/low growing lesions were present and were not causing functional and/or important aesthetical discomfort.

In patients who underwent surgical treatment, radical resection was performed in most cases (8/15 patients). However, the proportion of patients undergoing bone shaving increased (6% versus 15%), while a decrease in the number of patients undergoing radical surgery was seen (63% versus 19%). Optic canal nerve decompression was performed in one only long-standing symptomatic patient, and a small amount of visual improvement was observed. Radical resection of a mandibular lesion was performed in two cases of relapse (2/7 patients) after bone shaving (one case was performed at

Another centre). As previously reported, no relapse was observed after radical treatment.

Discussion

FD represents about 2.5% of all bone lesions and 7% of all benign bone tumours, with an incidence of 1:4000-1:10,000 with a slight female predilection; usually the disease arises in the first three decades of life and stabilises when patients reach skeletal maturity. In most cases of CFD, the first clinical manifestation is a slow growing, eventually painful mass causing facial asymmetry. Pathological fractures, orbital dystopia, diplopia, proptosis, blindness, epiphora, strabismus, facial paralysis, loss of hearing, tinnitus and nasal obstruction, may also be evident. These lesions can infrequently present rapid growth and can be associated with other pathological lesions such as mucoceles or aneurysmal bone cysts, while malignant transformation is very rare (<1% of cases). On the basis of clinical behaviour, lesions can be classified as:
- quiescent (stable with no growth);
- non-aggressive (slow growing);
- aggressive (rapid growth +/- pain, para-aesthesia, pathological fracture, malignant transformation, and association with secondary lesions).

Diagnosis can be made with X-ray and CT-scan, but an incisional biopsy is mandatory. Once FD is confirmed, it is important to exclude PFD and MAS. Serum alkaline phosphatase is an important marker in detecting recurrence of FD. In most cases of CFD, the first clinical manifestation is a slow growing, eventually painful mass causing facial asymmetry. Pathological fractures, orbital dystopia, diplopia, proptosis, blindness, epiphora, strabismus, facial paralysis, loss of hearing, tinnitus and nasal obstruction, may also be evident. These lesions can infrequently present rapid growth and can be associated with other pathological lesions such as mucoceles or aneurysmal bone cysts, while malignant transformation is very rare (<1% of cases). On the basis of clinical behaviour, lesions can be classified as:

As previously reported, we only partially agree with the algorithm proposed by Chen, since free flaps allow optimal results in the reconstruction of Zone 4 defects; nevertheless, at present, we have partially changed our opinion about the treatment of stable lesions involving Zones 1 and 4. Another detailed description of CFD management according to anatomical sites has been recently proposed by Lee et al. In this study, we present our algorithm based on pathological behaviour and symptoms.

a) Facial deformities

Most patients affected by CFD present a slow growing, indolent mass, and facial deformity is the only symptom. In most cases, disease progression stops once skeletal maturity has been achieved, but reactivation of the disease has been observed in adulthood and during pregnancy. Even in MAS cases, skull lesions preferentially do not progress after puberty. Deformities are more disfiguring than in MFD and PFD, particularly if GH excess is untreated or inadequately treated. Management of FD depends on the anatomical site as well as on clinical and biological characteristics of lesions, but, especially in younger patients, it is impossible to predict it since no biomarkers or specific histological characteristics exist. In those latter cases, watching carefully and attentively is the best option. It is preferable to perform any
kind of surgery only after puberty, but sometimes it is necessary to operate on the patient earlier.

One of the main question concerns is the treatment choice and whether it is easier to treat an adult or a child. In our previous paper, we recommended wide resection and contemporary reconstruction in cases of Zones 1 and 4 lesions even in younger children. While in cases of Zone 1 defects, reconstruction can be achieved in most cases using bone grafts and/or local flaps; in cases of Zone 4 defects, free flaps are preferential as they can assure adequate reconstruction, but in younger patients their use should be discussed. It is clear that it is more important to distinguish between adult (>14 years) and paediatric (<14 years) patients than between stable (quiescent/non-aggressive) and growing (aggressive) lesions. Considering both adult and paediatric populations with cases of stable lesions, we currently recommend remodelling as the primary treatment (Figs. 2A and B). It is true that a major rate of recurrence is reported after bone shaving, but it can be repeated.

An adequate follow-up (annual CT scan for the first two years and then based on of clinical findings) makes it possible to identify relapse and to treat it early. Obviously, in those latter cases the treatment of choice is surgical resection and contemporary reconstruction. The change in the treatment of stable lesions in adult patients is due to the fact that wide resection always requires reconstruction; this can lead to higher post-operative morbidity in terms of recovery time when compared to surgical shaving, even if the aesthetical and functional results are considered better.

Based on our advice, it is mandatory to inform the patient about the therapeutic options. In most cases, remodelling is the favoured choice. This is probably due to the fact that most patients prefer to try to obtain aesthetical and functional improvements with a less complex surgical intervention, knowing that in case of a relapse radical surgery can be performed.

In previous studies, reports on recurrence do not differentiate between stable and growing lesions; it can be hypothesised that in the first cases the expected recurrence rate would be lower. In paediatric patients, remodelling permits the clinician to avoid influencing craniofacial growth and asymmetry. Currently, surgical shaving can be optimised using computer-assisted navigation. Mirror techniques permit achieving optimal aesthetic results, but there appear to be some disadvantages. The main one is the absence of instruments in some centres. Due to the low use in maxillofacial surgery, operative time is higher than with conventional techniques.
In cases of aggressive lesions, it seems the best therapeutic option is surgical resection and contemporary reconstruction; nevertheless, in the case of paediatric patients each case has to be carefully evaluated according to several parameters:

- wide resection (mostly if altering occlusion) leads to some degree of facial asymmetry regardless of reconstruction;
- donor site morbidity must be considered.

We have to distinguish between two main situations:

- **Small residual defects**: Reconstruction can be achieved using local flaps or bone grafts, so that a radical resection can be considered. Since radiotherapy is not considered, treatment for CFD, complications related to bone grafts and absorption due to irradiation can be excluded. The best option in cases of mandibular reconstruction is the use of an autogenous rib graft. Such cases may require further surgical intervention (eventually with a free flap reconstruction) once skeletal maturity has been reached in order to permit implantoprosthetic rehabilitation. In this group with Zone 1 defects, in which bone graft reconstruction leads in most cases to adequate results, can be included.\(^{16,25,26}\)

- **Large residual defects**: Even an adequate reconstruction can lead to facial asymmetry, and remodelling as the first choice should be considered, eventually delaying a more aggressive surgical intervention after puberty. Currently, free-tissue transfer has become the preferred treatment option for reconstruction of extensive tissue; iliac crest and fibula free flaps appear to be the best options in cases of Zones 1 and 4 defects in adults. Nevertheless, some considerations have to be made in younger patients, since the recipient vessels are much more prone to vasospasm compared to those in adults. In addition, one must consider growth alteration at the donor site. Iliac crest free flap is not considered before skeletal maturity has been reached.\(^{20}\) Fibula free flaps are the best choice, and donor-site morbidity can be minimised in most cases with attention to technical details of fibular flap harvesting and use of aggressive physical therapy.\(^{27}\) Nevertheless, even if some authors advocate its use also in younger patients (< 9 years), we think that in cases of surgical resection for malignant lesions immediate reconstruction using fibula free flap can be justified, but in FD cases this option has to be considered only after failure of primary reconstruction using bone grafts or in case of relapse after remodelling has occurred.

**b) Trigeminal nerve impairment**

Growing lesions can result in compression of the adjacent structure such as the trigeminal nerve; patients refer hypo-anaesthesia or para-aesthesia, but in some cases they complain of hyperaesthesia. In such cases, surgical decompression of the canal nerve has been described.\(^{28}\) Nevertheless, this procedure cannot be definitive; in such cases, more aggressive intervention consisting of nerve interruption at the Spix or infraorbital foramen may be required. In order to restore sensitivity of the lip and teeth, a microsurgical anastomosis with the contralateral mandibular nerve can be performed at the same surgical time (Fig. 3). In cases of infraorbital nerve impairment, anastomosis can be performed using a nerve graft.\(^{29}\)

**c) Sinusitis**

Between the paranasal sinuses, the sphenoid sinus is the most frequently affected by FD.\(^{8,30}\) Nevertheless, the incidence of sinusitis in patients affected by FD is the same when compared with the general population.\(^{8}\) The treatment is the same and consists of a combination of surgery and medical therapy (Fig. 4A); obviously, surgery is necessary to correct anatomical alterations causing obstruction or associated lesions such as mucocele.\(^{18}\) A preferential approach, as in the general population, is an endoscopic one.\(^{31}\) If aesthetical corrections are needed,
Our experience in the surgical management of craniofacial fibrous dysplasia: what has changed in the last 10 years?

In cases of recurrent sinonasal infection, particular attention must be paid to avoid complications such as osteomyelitis. In such cases, surgical resection is required. In patients affected by FD, osteomyelitis is one of the complications that can arise. It is most frequent in case of lesions involving the maxilla and mandible derived from dental infections or recurrent sinusitis. Diagnosis can be difficult, since only histological examination can confirm it in most cases. It is very challenging to treat. Medical therapy is mandatory, but to resolve the pathology, surgical resection (Fig. 4B) is usually required. It is known that caries index scores are higher in patients affected by FD, and this has been attributed to enamel hypoplasia and hypomineralisation, and also to limited dental care. In cases of dental infection, it is mandatory to extract or treat the teeth, but in these cases healing can be altered thus increasing the risk of osteomyelitis.

Diplopia/exophthalmos

Orbital bone involvement in cases of CFD can lead to midfacial asymmetry or hypertelorism, exophthalmos and proptosis (in cases of anterior skull base and frontal bone involvement); diplopia can be referred. In the first case, treatment is described in the section “Facial deformities” and consists of remodelling in cases of stable lesions and wide resection in cases of aggressive ones. When massive involvement of the orbital bones is observed, an interdisciplinary approach is mandatory to evaluate the presence of ophthalmological complications such as diplopia and visual impairment. In surgical treatment of exophthalmos consequent to FD, it must be considered that remodelling of maxilla and zygoma can lead to a worsening of symptoms. In those cases, surgical osteotomies to improve orbital volume should be performed (Fig. 5A). If only a 2-wall decompression is required, an endoscopic approach has to be considered. Obviously, maxillo-zygomatic correction must be considered at the same surgical time. In order to treat diplopia, the first step is to correct orbital dystopia; eventually, eye muscle realignment surgery can be performed.

Optic nerve compression (ONC)

CFD involving the anterior cranial base and sphenoid bone can encase the optic nerve, but does not always result in visual loss. It is already accepted that loss of vision consequent to optic canal nerve involvement can be due to several factors, including direct compression, optic nerve traction (proptosis), haemorrhage/injury of the optic nerve and FD-associated cystic lesions. Recently, a meta-analysis concluded that most patients affected by CFD with radiographic optic nerve compression are asymptomatic and will remain that way, so that “…surgical decompression should be reserved for symptomatic patients, the majority of whom will show improvement and good long-term results after optic nerve decompression. Expectant management, repeated ophthalmologic exams, and long-term radiologic follow-up are indicated in asymptomatic FD patients who have optic nerve encasement.” In cases in which decompression is required, we agree with Schreiber et al (Fig. 5B), who stated that “…endoscopic optic nerve decompression has become widespread.
ly accepted as the approach of choice for post-traumatic injuries and subsequently for benign lesions compressing the nerve and accessible through the nose, such as fibrous dysplasia” [18]. Open surgery is reserved for cases in which a need for frontal bone or other anterior cranial base remodelling is required; obviously, a combined approach should eventually be considered.

Conclusions

Fibrous dysplasia is a benign disease and radical resection (if possible) is the only technique to obtain resolution of the disease. Watching carefully and attentively is indicated in cases of stable lesions, and based on our experience, it is the best therapeutic option if possible. Current reconstructive techniques allow achieving adequate aesthetic and functional results; nevertheless, in most cases adjunctive surgical refinements are required and recovery times are higher than in cases of surgical shaving, so that most patients prefer to undergo remodelling. Nevertheless, in cases of aggressive lesions we think that radical resection is mandatory, except in paediatric patients with residual large defects. In these cases, we think that it is acceptable to try and resolve symptoms by performing bone shaving, reserving more aggressive treatment for cases of relapse or after skeletal maturity.

Injection laryngoplasty through a transoral approach using the Guedel oral airway

Laringoplastica iniettiva mediante approccio transorale con l’utilizzo della cannula di Guedel

SUMMARY

Injection laryngoplasty has gained popularity as a treatment modality for glottal insufficiency. Several approaches have been described, specifically transcutaneous, transoral and transnasal. The authors describe a novel technique performed successfully on three subjects, namely endoscopic injection laryngoplasty using the modified Guedel oral airway. There was marked improvement in dysphonia, maximum phonation time and closed quotient in all three subjects with a decrease in the Voice Handicap Index-10 score. This new approach is a viable approach for the treatment of glottal insufficiency.

KEY WORDS: Glottic insufficiency • Laryngoplasty • Endoscopy

INTRODUCTION

Injection laryngoplasty has gained popularity among otolaryngologists as a treatment modality for glottic insufficiency. The main approaches are the transcutaneous, transoral and transnasal. The transoral approach is primarily limited by the presence of hyperactive gag reflex and/or inadequate oral opening, whereas the transcutaneous approach is limited by unfavourable neck anatomy. In both approaches two routes are used, one for visualising the larynx and the other for introducing the injecting needle. In addition, there is a need for an experienced assistant to perform the flexible endoscopy 12. On the other hand, transnasal injection laryngoplasty as described by Ricci Maccarini A et al. is a safe procedure with limited discomfort to the patient 3. Nevertheless, it has limited application in cases of a narrow nasal passage, especially in patients who are on anticoagulants 3.

The authors describe a novel approach, namely fibre optic endoscopic injection laryngoplasty through the transoral approach using the modified Guedel oral airway 4 (Fig. 1). This approach can be used as alternative to the aforementioned conventional approaches.

This investigation was exempted from the Institutional Review Board Approval. While the patient was seated in the examination room, the oral cavity, oropharynx and larynx were anesthetised by applying xylocaine spray and gel to the dorsum of the tongue, following which the modified Guedel oral airway was inserted. The fibre optic scope with working channel (Ref 11001UD1 by Karl Storz) was then gently introduced thru the oral airway until the laryngeal structures were visualised (Fig. 2). Similar to the transnasal approach, once the fibre optic scope was in place, a 19 gauge fibre optic needle (Endoline Securline – BTC Medical Europe S.R.L., made in Italy) was then introduced through the working channel of the endoscope and its blunted tip was used to palpate the posterolateral and mid aspect of the vocal cord to ensure complete anaesthesia. The needle was then engaged at the desired injection site and filling material was injected until voice quality was satisfactory. The scope is usually handled with the right hand and the injecting needle in the left hand. The sy-
Injection laryngoplasty using the Guedel oral airway

Ring containing the filling materiel can be either pressed by the surgeon or by the assistant. Patients were instructed to resume oral intake one hour after the procedure to avoid risk of aspiration. Pooling of secretions in the larynx was reduced by administering intramuscular glucopyrrolate (200 micrograms/1 ml) prior to the procedure.

Case series

Patient selection for this approach was based on the presence of either a strong gag reflex (patient 1), intake of anticoagulants and/or the presence of a narrow nasal passage (patients 2 and 3). The first patient was a 23-year-old man with dysphonia and aspiration secondary to an immobile right vocal cord and impaired mobility of the left cord following prolonged intubation that resulted in subglottic scarring. The second patient was a 60-year-old woman with dysphonia and dysphagia secondary to an immobile right vocal cord post resection of a right cerebellopontine angle tumour. The third patient was a 65-year-old woman with dysphonia and dysphagia secondary to a left immobile vocal cord following total thyroidectomy. In all three patients, 0.2 to 0.6 cc of Restylane® (hyaluronic acid stabilised solution 20 mg/ml) was injected lateral to the vocal process and/or at the mid vocal cord. Perceptual evaluation, maximum phonation time, as well as closed quotient and Voice Handicap Index-10 were used as outcome measures.

This novel approach was well tolerated by all patients with no complications. In all three subjects, there was marked improvement in all perceptual parameters (Table I) with an increase in the maximum phonation time by 8 seconds in the first patient, 7 seconds in the second patient and 5.5 seconds in the third. There was also a noticeable decrease in the Voice Handicap Index-10 score in the three subjects (Table II).

The mean closed quotient, measured by computing the ratio of closed frames to the total number of frames, improved from 0 to 0.4 in subject one, from 0.3 to 0.5 in subject two and from 0.4 to 0.5 in subject three.

Discussion

Injection laryngoplasty as an office procedure has become the gold standard treatment of glottic insufficiency. There are ubiquitous reports on the added value of the different approaches used with the main focus being on tolerance, safety and improvement in voice quality and swallowing. As a novel approach, we have combined the usage of the transnasal fibre optic endoscope/working channel with the modified Guedel oral airway primarily used in gastroscopy and bronchoscopy. The added values of this novel approach are; 1, the use of only one route for visualisation of the larynx and introduction of the injecting needle unlike the transoral and transcAdamaneous approaches; 2, the

Use of the modified oral airway facilitates the introduction of the fibre optic endoscope and guides its pathway to the laryngeal inlet with no difficulty or discomfort to the patient as the scope slides on the lingual surface of the oral airway with little if any contact with the mucosa; 3, the fibre optic scope secures the passage of the injection needle through the endoscope working channel thus preventing inadvertent injury to the pharyngeal mucosa; 4, it allows the surgeons to use both hands with no need for an experienced assistant to do the fibre optic endoscopy or for the patient to hold his or her tongue. The scope is usually held by the surgeon’s left hand and the fibre optic needle is held in the right hand. It is important to note that the fibre optic scope can be easily maneuvered through the oral airway because of the enhanced rotation along its longitudinal access achieved by the removal of the dorsal convex roof. Another advantage is the lack of risk for the patient to bite the scope by accident.

**Conclusions**

This approach is a viable alternative to the transoral, transcutaneous and transnasal approaches. It is of particular added value to the transcutaneous approach in patients with unfavourable neck anatomy, to the transoral approach in patients with a strong gag reflex and to the transnasal approach in patients with narrow nasal passages and/or are on anticoagulants.
